Foreword, xv

Dedication, xvi

Preface, xvii

About the companion website, xviii

Part I: Basic science and principles

- 1** Wound healing and scar formation, 3
Simon R. Myers and Ali M. Ghanem
- 2** Basic skin flaps and blood supply, 12
Edwin J. Morrison and Wayne A.J. Morrison
- 3** Biomaterials and structural fat grafting, 22
Naghmeh Naderi, Behzad Ardehali and Afshin Mosahebi
- 4** Local anaesthetics, 34
Yasamin Ziabari
- 5** Lasers, 44
Se-Hwang Liew
- 6** Tissue expansion, 51
Dariusz Nikkhah, Lara Yildirimer and Neil W. Bulstrode
- 7** Tissue engineering, 62
Lara Yildirimer and Alexander Seifalian

Part II: Integument

- 8** Skin structure, 79
Anthony Barker
- 9** Melanoma, 88
Carlo Riccardo Rossi and Antonio Sommariva
- 10** Non-melanoma skin cancers, 100
Michael Findlay and Mina S. Ally
- 11** Atypical skin lesions, 115
Michael Findlay and Michael A. Henderson
- 12** Allotransplantation, 130
Maria Siemionow and Fatih Zor

- 13** Radiation therapy and soft tissue response, 144
Gurdip Kaur Azad and Carie Corner

- 14** Burns: acute care and reconstruction, 153
Peter Dziewulski

Part III: Paediatric plastic surgery and congenital disorders

- 15** Congenital melanocytic naevi, 183
Sabrina Cugno, Veronica Kinsler and Neil W. Bulstrode
- 16** Vascular anomalies, 192
Sabrina Cugno, Alex Barnacle, John Harper and Neil W. Bulstrode
- 17** Cleft lip, 204
Marc C. Swan and David M. Fisher
- 18** Cleft palate and velopharyngeal dysfunction, 219
Sabrina Cugno and Brian C. Sommerlad
- 19** Congenital ear anomalies, 238
Sabrina Cugno and Neil W. Bulstrode
- 20** Craniofacial clefts, 255
Irene M.J. Mathijssen and Sarah L. Versnel
- 21** Craniosynostosis, 264
Aina V.H. Greig and David J. Dunaway
- 22** Orthognathic surgery, 279
Tim Lloyd, Ravinder Pabla, Sujata Sharma and Nigel Hunt
- 23** Facial reanimation, 295
Jonathan I. Leckenby and Adriaan O. Grobbelaar

Part IV: Head and neck reconstruction

- 24** Head and neck malignancy: staging and neck dissections, 309
Andrew N. Morritt, Marlene S. See and Navid Jallali
- 25** Oral tongue reconstruction, 318
Stuart Archibald, Michael Gupta and Achilles Thoma
- 26** Mandibular reconstruction, 330
Christopher Glenn Wallace, Chung-Kan Tsao and Fu-Chan Wei

- 27** Maxillary reconstruction, 338
Achilleas Thoma, Michael Gupta and Stuart Archibald
- 28** Pharyngeal reconstruction, 349
Ross D. Farhadieh and Wayne A.J. Morrison
- 29** Skull base reconstruction, 362
Ross D. Farhadieh and Wayne A.J. Morrison
- 30** Cheek reconstruction, 366
Adam C. Gascoigne and Ross D. Farhadieh
- 31** Lip reconstruction, 377
Marlene S. See, Andrew N. Morritt and Navid Jallali
- 32** Nasal reconstruction, 390
Jean-Brice Duron and Marc Revol
- 33** Eyelid reconstruction, 407
Konal Saha and Naresh Joshi
- 34** Ear reconstruction, 416
Françoise Firmin and Neil W. Bulstrode
- 35** Scalp and calvarial reconstruction, 427
Christopher Glenn Wallace and Fu-Chan Wei
- 36** Facial trauma, 437
David David

Part V: Breast

- 37** Anatomy and physiology of the breast, 479
Giovanni Bistoni and Jian Farhadi
- 38** Breast augmentation, 486
Ross D. Farhadieh and Jian Farhadi
- 39** Breast reconstruction, 499
Phillip Blondeel, Maria Athanasiadou and Andreas Tromaropoulos
- 40** Gynaecomastia and tuberous breast, 519
Afshin Mosahebi and Amir Sadri
- 41** Mastopexy and breast reduction, 530
Elizabeth J. Hall-Findlay

Part VI: Trunk and lower limb

- 42** Chest wall reconstruction, 551
Mazyar Kanani and Martin J. Elliott
Simon Withey and Robert Pearl
- 43** Abdominal wall reconstruction, 564
William A. Townley and Stefan O.P. Hofer
- 44** Genitourinary and perineal reconstruction, 575
Niri S. Niranjani
Paige Fox, Paul Mittermiller and Gordon K. Lee
Kathryn Evans and Imran Mushtaq

- 45** Pressure sores, 597
Adam C. Gascoigne and Stephen Flood
- 46** Lower limb reconstruction, 607
James K. Chan, Matthew D. Gardiner, Michael Pearse and Jagdeep Nanchahal
- 47** Lymphoedema, 628
Kelvin Ramsey and Peter Mortimer

Part VII: Upper limb

- 48** Hand examination and investigations, 645
J. Henk Coert, Peter Hoogvliet and Willem D. Rinkel
- 49** Congenital hand differences, 660
Bran Sivakumar, Jonathan Adamthwaite and Paul Smith
- 50** Finger tip injuries, 688
Donald Sammut and Robert Pearl
- 51** Flexor tendon injuries, 707
Sarah Tucker and Georgina Williams
- 52** Extensor tendon injuries, 722
Gregory McCarten
- 53** Tendon transfers, 733
Adam C. Gascoigne and Stephen Flood
- 54** Amputations, replantation and thumb reconstruction, 752
Gráinne Bourke
- 55** Compartment syndrome in the extremities, 769
Steven E.R. Hovius and Tim H.J. Nijhuis
- 56** Nerve injury, repair and reconstruction, 777
Renata V. Weber, Andrew Yee, Michael M. Bottros and Susan E. Mackinnon
- 57** Brachial plexus injuries and reanimation, 797
Kirsty U. Boyd, Kristen M. Davidge and Susan E. Mackinnon
- 58** Nerve compressions, 813
Kristen M. Davidge and Susan E. Mackinnon
- 59** Dupuytren disease, 838
Paul M.N. Werker
- 60** Fractures and dislocations in the hand, 850
Barbara Jemec and Nicola Burr
- 61** Osteoarthritis and prosthetic joints in the hand, 861
Adam C. Watts and Ian A. Trail
- 62** Wrist pathology, 878
Owen L. Ala, T. Shane Johnson and L. Scott Levin
- 63** Rheumatoid arthritis of the hand and wrist, 890
Rebecca Ayers and Mark Pickford

- 64** Lesions of the hand, 904
Richard D. Lawson, David A. Stewart and Michael A. Tonkin

Part VIII: Aesthetic surgery

- 65** Facial anatomy and ageing, 923
Chin-Ho Wong and Bryan C. Mendelson
- 66** Non-operative facial rejuvenation, 940
Jean Carruthers and Alastair Carruthers
- 67** Forehead lift, 948
Timothy J. Marten and Dino Elyassnia
- 68** Upper eyelid rejuvenation, 967
Adil Ceydeli, Tong C. Duong and Robert S. Flowers
- 69** Lower eyelid–cheek junction rejuvenation, 976
Sam T. Hamra
- 70** Facelift, 992
Bryan C. Mendelson and Ross D. Farhadieh
- 71** Neck lift, 1004
Timothy J. Marten and Dino Elyassnia
- 72** Rhinoplasty, 1032
David Stepnick, Catherine Weng and Bahman Guyuron

- 73** Genioplasty, 1047
Nicholas Lee, Deepak Komath and Tim Lloyd

- 74** Blepharoptosis, 1063
Alan A. McNab

- 75** Liposuction and liposculpture, 1075
Darryl J. Hodgkinson

- 76** Abdominoplasty and body contouring, 1083
Alexander Stoff and Dirk F. Richter

Part IX: Military, simulation training and exams

- 77** Simulation learning in plastic surgery, 1107
Ali M. Ghanem and Simon R. Myers
- 78** Military plastic surgery, 1121
Robert M.T. Staruch and Shehan Hettiaratchy
- 79** Plastic surgery fellowship and board exams, 1129
Robert Pearl, Youssef Tahiri, Sabrina Cugno and Ross D. Farhadieh

Index, 1135

Foreword

Plastic surgery is a unique specialty, defined by concept rather than anatomical area. As such, it has grown enormously over the last 70 years and continues to evolve with changes in technology, improved understanding of anatomy and patient-centred outcomes. This progression leads to a vast and ever increasing array of new techniques and options for reconstruction, benefiting both our patients and the many other medical and surgical specialties that consult the plastic surgeon. With many tools at their disposal and the wide array of clinical maladies that they treat, the plastic surgeon has evolved into a problem solver. This synergy between plastic surgery and other surgical specialties has enabled these other specialties to utilize the problem-solving skills of the plastic surgeon to expand their therapeutic spectrum and tackle increasingly more difficult problems. However, to be an effective problem solver it is incumbent on the plastic surgeon to be familiar with the latest developments of our broad and expanding field. This highlights the necessity of a single-volume text that is comprehensive and practical, covering the full spectrum of plastic surgery and presenting the current state of the art of our specialty. This is exactly what the editors of *Plastic and reconstructive surgery: Approaches and techniques* set out to achieve in producing this excellent textbook.

It is truly an international effort at all levels, as the editors, from Australia (Ross D. Farhadieh), the UK (Neil W. Bulstrode) and Canada (Sabrina Cugno), have joined forces to recruit over 130 international contributors and produce a resource of over 1100 pages that provides a well-organized and thorough, yet succinct, text of the essentials of current plastic surgery. The editors are all highly qualified and accomplished young plastic surgeons, and they have been able to provide a global perspective of our specialty. Many of the contributors are world-renowned experts; however, there is also a new generation of young rising stars whose contributions are equally good, providing a new, fresh and contemporary feel.

Each chapter is clearly organized and provides an overview of the principles and the most recently described basic science essentials, as well as clinical applications and techniques, and pertinent bibliography for additional reading. The critical core information is provided for each topic, providing an excellent synopsis and reference for the student and practitioner.

Although aimed primarily at the trainee, I believe that it will also serve as an excellent and quick reference for the seasoned practising surgeon faced with complex problems requiring reconstruction throughout the body. It will also be an especially useful resource for senior plastic surgery trainees preparing to take their Board and Fellowship exams. The final chapter, dealing specifically with the certification process and fellowship exams, is interesting, and provides useful information and different perspectives of the qualifying processes in the British, European, Australian and North American systems.

It has been an honour and pleasure for me to have been asked to contribute the Foreword to this new textbook, which very nicely fulfills one of the traditions of surgery of passing down knowledge from one generation of problem solvers to the next. The new generation is likely to face even more complex problems and, using the latest techniques, solve them more elegantly than we can now. But the principles in plastic surgery never change, and this textbook provides the intrinsic fundamentals that all trainees must know, even as the field is ever expanding.

I congratulate the editors for their Herculean effort in recruiting an international cast of distinguished surgeons and thank the authors for flawlessly summarizing the huge avalanche of new information that has graced our specialty; finally, I thank the publishers, Wiley Blackwell, for producing this timely, impressive and comprehensive plastic surgery compendium.

Julian J. Pribaz
Professor of Surgery
Harvard Medical School

Dedication

To inspirational mentors and dedicated apprentices everywhere.

Preface

During my plastic surgery training there appeared to be a plethora of summary and broad-stroke single-volume plastic surgery textbooks, all of which lacked adequate detail. Conversely I would encounter multivolume behemoths, detailed reference texts that always seemed leaden and difficult to digest. In my experience neither of these options fully addressed the needs of a trainee surgeon, or for that matter a more senior surgeon. Thus was born, on a long flight from Sydney to London, the notion of compiling a single-volume textbook that seeks to achieve the perfect balance of detail and palatability. To that end, in compiling this textbook we approached some of the world's leading authorities in the various fields of plastic surgery. This was with the belief that not only could readers benefit from such experts' enormous experience, but they could also gain practical insights from the ability of such experts to sift through the ever increasing volume of literature and distil what is relevant and applicable to everyday practice.

My co-conspirators in this endeavour, Mr Neil Bulstrode from Great Ormond Street and Dr Sabrina Cugno from Montreal Children's Hospital, had the perfect blend of enthusiasm and sense of humour to see this work through. I am grateful to them for their advice, time, effort and, most importantly, their friendship, all of which made this compendium possible. I also wish to thank all of our colleagues who took time out of their busy lives to make this volume possible. It has been an extraordinary experience for all of us to collaborate on this project. Our special thanks go to Professor Julian Pribaz for

being kind enough to review the volume and write the Foreword. We also wish to thank Wiley Blackwell for their continued support for this project.

On a personal note I wish to thank my mother Tadjvar, my brother Arash and wife Yassi for enduring me during the last 2 years, and for their unwavering support. My parents have been my guiding light in demonstrating the importance of a strong work ethic and integrity. I also wish to thank Messrs Neil Bulstrode and Adriaan Grobbelaar for the extraordinary fellowship opportunities and friendship they have afforded me. I am very grateful to Messrs Ash Mosahebi and Jian Farhadi, who kindly accommodated me in their operating theatres and taught me a great deal about the art of plastic surgery. In Melbourne I wish to extend my sincere thanks to Mr Bryan Mendelson, who during my visits showed immense patience and generosity in teaching me the philosophy and techniques of facial aesthetic surgery. My gratitude also goes to Mr Stephen Flood, who illustrated by example a sensible approach to plastic surgery and kindness in mentorship; this continues to serve as an aspiration. As a plastic surgeon I am most indebted to Professor Wayne Morrison, who has curiosity, humility, dedication to teaching and generosity of will and spirit, tempered with a crisp sense of humour, in equal inspirational measure. It was truly an honour and a privilege to serve as his registrar.

CHAPTER 1

Wound healing and scar formation

Simon R. Myers and Ali M. Ghanem

Department of Plastic Surgery, Barts and the London School of Medicine and Dentistry, London, UK

TYPE I – CLASSICAL CUTANEOUS WOUND HEALING

A wound, in the context of skin, is a breach in the barrier that distinguishes an organism from its environment. The process through which the organism works in order to address this breach is 'wound healing' which, because of the important role the skin plays in the survival of the organism, is quite literally vital, and conserved through evolution. In the normal course of events, a lower species accepts tissue loss and heals a wound by exposure, licking, picking and, at the molecular level, scarring. The single most important impact on wound healing in humans is the early closure of wounds, by apposition with sutures in incisional wounds, and skin replacement in excisional wounds. Humans can deny significant skin and composite tissue loss by a 'like for like' replacement in the specialty of plastic and reconstructive surgery, and here we can boast a form of 'supranormal wound healing'.¹

Wound healing classifications

There are many ways to classify wound healing. In simple terms, we can consider:

- four phases – coagulation, inflammation, fibroplasia and remodeling;
- four types – fetal, adult, acute and chronic;
- four ages – young, plateau, regressing, atrophic; and
- two systems of healing – epidermal and dermal.

We can also classify wound healing in terms of clinical features and their wound management.

Phases of wound healing

Wound healing can be considered a process of four sequential but overlapping phases by which the body closes a breach in tissue continuity. There are many ways to define such a complex

process. Key to understanding the standard classification of the process is a consideration of: the timing, the cellular activation or influx and the chemical mediators.²

Coagulation

This *immediate* response to cutaneous injury involves two cascades: the clotting cascade, with the formation of platelet clot which adheres to the collagen exposed following endothelial disruption; and the complement cascade and complement-mediated vasodilatation. Histamine (released by mast cell degranulation) and kinins contribute to vasodilatation and increased vascular permeability. The first cells involved then are platelets and mast cells, and the first mediators histamine, kinins, platelet-derived growth factor (PDGF) and transforming growth factor beta (TGF- β). The increasing interest in platelet-rich plasma (PRP) clinically in regenerative medicine is based on these early cascades.

Inflammation

Between the time of injury and around 4 days post injury, the clinical signs of inflammation develop. Classically these are redness, swelling, pain and loss of function. These result from inflammatory mediators and the capillary leak into the extracellular space that they coordinate. The next inflammatory cell type to arrive at the wound is the macrophage, followed by neutrophils and then lymphocytes. Keratinocytes in the wound edge and follicle remnants migrate and proliferate, and fibroblasts are chemo-attracted, and become activated.

Fibroplasia

From day 4, and for 2–4 weeks, the wound bed becomes vascularized, and type III collagen is laid down by fibroblasts to replace any dermal loss. In the absence of epidermal cover, this appears clinically as granulation tissue. Closed wounds become red and raised for a while. Hydrated glycosaminoglycans form a ground substance for the collagen fibrils. This phase is characterized by fibroblast proliferation, but also by keratinocyte proliferation.

Remodelling

From a few weeks to 18 months or more, the wound goes through a long phase of remodeling. Fibroblasts mature into myofibroblasts to contract the wound. Type III collagen is gradually replaced by type I collagen. Disorganized collagen becomes lamellar.

Repair versus regeneration

There are significant differences between the wound healing seen in fetal life and that seen in postnatal life. So-called scarless healing occurs for a period in the fetus, however this is not absolute but dependent on gestational age and wound size.³ In late fetal life scarring does occur, and before this point in time, a large enough wound will still result in scarring. In postnatal life, scarring is the inevitable and permanent consequence of wounding beyond the epidermal basement membrane. An adult lower vertebrate such as a salamander can regenerate an amputated limb but will not aspire to climb Mount Everest or graduate from Oxford! Although regenerative medicine attempts to harness the same plasticity seen in lower vertebrate regeneration, what is generally achieved is only 'partial regeneration', and not replacement of like with like. The ongoing concern in work to manipulate adult/somatic stem cells to achieve true regeneration is around a loss of control and the risk of carcinogenesis.

Acute versus chronic wound healing

Acute wound healing is hard to distinguish absolutely from chronic wound healing, and the processes at a cell and molecular level may be similar.⁴ Chronic wound healing occurs when healing takes longer than might be anticipated in a fit, healthy person, and is often associated with comorbidity. Such wounds seem to become stuck in the inflammatory or proliferative/fibroplastic phases. Local wound management can only usefully begin following an assessment and optimization of systemic comorbid conditions.

Epithelial/epidermal versus mesenchymal/dermal wound healing

The epidermis provides the ultimate barrier between the body and environment. The main cell type is the keratinocyte. Regeneration occurs from a population of follicle stem cells.⁵ The dermis provides the structural support to the epidermis and other related adnexae. The main dermal cell type is the fibroblast. As in embryogenesis, there is ongoing 'cross-talk' between the epidermis and dermis in somatic cutaneous wound healing, the epidermal element of which has been relatively underplayed. Even less consideration has been given to the contribution of subcutaneous fat to cross-talk.

Wound healing and scarring

In many ways, wound healing and scarring are inseparable – the one leads to the other at some level and over time. When does a wound become a scar? That will probably depend at a molecular level on very early wounding and wound management events. Although a scar is the inevitable and permanent consequence of postnatal wounding beyond the basement membrane and a compromise between regeneration and repair, at a clinical level, its significance is largely patient related and subjective. This can now be captured clinically by the Patient and Observer Scar Assessment Scale (POSAS), which draws patients into their own management.⁶

Most patients would perceive a wound as a scar from the time that the wound is no longer open, and often that equates to the absence of exudate and any requirement for dressing care. Clinically, even a normotrophic scar will go through a natural progression to maturity. When young, it will be active. Most young scars exhibit features of hypertrophy. Most scars then go through a plateau period of relatively little clinical change in the absence of treatment. Most scars then go through a period of regression of inflammatory signs and symptoms, and eventually settle to a mature state. Some scars, after many months or years, and sometimes because of treatment, become very thin, pale and atrophic.

When then does a normotrophic scar become a pathological scar? A normotrophic scar results from uneventful primary healing, but there is wide variation with age, site and skin type, and a period of hypertrophy is not unusual. Hypertrophic scarring is classically seen in paediatric burn wounds that have struggled to heal.⁷ The scar becomes red, raised, painful and itchy around 2–3 months following wound closure, particularly in wounds that have taken more than three weeks to heal. The scar settles over 18 months to 2 years, but often incompletely. Hypertrophic scars occur particularly in extreme Fitzpatrick skin types. Presumably, there is a bell curve distribution within the population, where those at the extreme end of hypertrophic scarring could be termed pathological. Although a keloid scar shares many of the features of a hypertrophic scar, and may represent an extreme example of the same, it is defined by extension beyond the confines of the injury, by almost inevitable progression beyond 2 years, seldom regressing; by being refractory to most treatments and recurring within 4–6 months of cessation of most treatments; and by behaving pathologically like a benign tumour. Understanding such an extreme phenotype may prove key to the effective management of more normotrophic scarring.

Epidermal wound healing

Adult epidermal stem cell biology is relatively well understood. Keratinocyte stem cells reside primarily in the bulge region of the hair follicle and, by asymmetric division, populate the interfollicular basement membrane with transit amplifying cells.⁸ These divide a number of times to provide the differentiating cells of the stratifying epidermis. A huge array of small

peptides are involved in coordinating the response to epidermal wounding by autocrine, paracrine and juxtacrine signaling.⁹ In a human model of epidermal healing, a number of phases of keratinocyte activity are suggested, as shown in Figure 1.1.¹⁰

Acute activation

Almost immediately following wounding, the epidermis expresses interleukin 1 β (IL-1 β) and interleukin 6 (IL-6) and the dermis TGF- β 1, committing transit amplifying cells to mitosis. Although TGF- β 1 is antiproliferative, it is pro-migratory to keratinocytes.¹¹

Early activation

Towards 24h following wounding, keratinocyte proliferation and migration are clear. Epidermal expression of TGF- α and IL-6 is accompanied by dermal fibroblast keratinocyte growth factor (KGF) and IL-6 expression. A paracrine loop of epidermal IL-1 β induction of the potent keratinocyte mitogen KGF from dermal fibroblasts seems likely.¹² TGF- α both is a keratinocyte mitogen and induces the migratory K6/K16 keratinocyte cyto-

skeletal phenotype in the suprabasal compartment.¹³ It may also recruit nearby follicles by juxtacrine signalling.¹⁴

Restitution

Over weeks, homeostasis is restored, with relatively late activation of the bulge to restore the transit amplifying population.

Dermal wound healing

Wound healing studies have concentrated far more on the dermis than epidermis, and particularly on macrophage production of TGF- β isoforms. This multifunctional growth factor appears to play a key role in dermal healing and scarring.¹⁵ Although the TGF- β 1 isoform promotes scarring, the TGF- β 3 isoform appears to have the opposite effect.¹⁶ Juvista (Avotermin) was developed to improve the quality of normotrophic scarring, but failed in a European phase 3 clinical trial.¹⁷ TGF- β , however, remains a key pharmaceutical target.

Figure 1.1 Temporo-spatial cytokine and growth factor gene expression in human suction blister wound healing. TGF, transforming growth factor; KGF, keratinocyte growth factor; relative OD, relative optical density.

A preoccupation with one growth factor, albeit a powerful, multifunctional factor with isoforms of different action, and for each a dose-dependent heterogeneity of responses, is arguably to ignore the complexity of wound healing cascades. There are many factors at play, often pleiotropic, and there is significant redundancy – so that many factors can contribute to the same outcome (i.e. rapid closure by scar). The growth factor that has shown most promise when delivered alone is PDGF.¹⁸

The dermis is far more than an extracellular matrix populated by fibroblasts. It hosts a vascular network (arterial, venous and lymphatic) and a neural network, and supports the follicle and other adnexal stem cell niches. It must also, it seems, interact with the subcutaneous fat. One approach to tissue engineering to provide for wound tissue loss is to synthesize an appropriate nanotechnology scaffold for key cellular elements to populate and develop. This can be *biofunctionalized* by incorporating a latent growth factor.¹⁹

Wounds can be classified based on clinical management and outcome as shown in Table 1.1.

'Normal'/primary incisional wound healing (type Ia)

Incisional wound healing occurs following surgical access, or 'incisional' or lacerating trauma.²⁰ In the former, the wound will begin sterile, and in the latter some degree of contamination is usual. In neither instance is there significant tissue loss. Classically, in modern medical practice, these wounds are formally closed,

although the timing of that closure will vary, affecting the quality of the healing processes and the scar that results.

Early closure (type lai)

If an incisional wound is closed directly, the healing will tend to be optimal. Elective surgical wounds are closed at the end of the procedure performed under sterile conditions. Traumatic lacerating wounds will generally be cleaned and closed the same day, and before significant bacterial colonization occurs. A relatively arbitrary time limit to early closure has evolved in practice of 48 h from injury. Beyond this, it is considered likely that colonization may be significant enough to deleteriously affect healing, and as a consequence the quality of scarring, which may become hypertrophic.

Late closure (type laii)

If a type Ia wound is sutured after 48 h, wound colonization may result in infection, dehiscence and delayed healing. Counterintuitively, according to current dogma if the wound is left open until day 4 or 5, as in 'delayed primary closure', satisfactory results can be achieved at a stage when the inflammatory response has become established – although a recent Cochrane review found no evidence for this.²¹

No closure (type laiii)

An incisional wound beyond the epidermal basement membrane that is left unclosed will gape and behave much like a deep excisional wound, healing by classical 'secondary intent'.²² The time

Table 1.1 A revised wound classification based on clinical management and outcome

Type I: Classical	Wound ± intervention	Character of healing
(a) 'Normal'/primary incisional – incisional, no tissue loss	(i) Closed early (<48 h)	Low risk of infection Minimal line scar
	(ii) Closed late (>48 h)	Increased risk infection Increased risk chronicity More significant scar
	(iii) Unclosed	Healing by granulation (similar to type Ibii), but in absence of tissue loss) High risk of chronicity
'Normal'/secondary excisional – tangential tissue loss, no replacement	(i) Above mid-dermis	Rapid re-epithelialization (<10 days) Minimal clinical scar
	(ii) Below mid-dermis	Slow/absent re-epithelialization High risk of infection and chronicity Closure by scar
Type II: Neoclassical		
(a) 'Supranormal' by skin replacement	(i) Early split- or full-thickness skin grafting of type Ibii)	Present gold standards Cosmetic and functional problems remain Donor defect
	(ii) Biotechnological skin replacements (Cuono technique, <i>in vitro</i> composite grafts)	Ideally autologous and with viable cellular elements Opportunity to improve on types Ibii and I lai
(b) 'Supranormal' with apparent acceptance of tissue loss	(i) Type Ibi treated with cultured keratinocyte allografts or vapour-permeable membrane	Follicle recruitment by activated extended follicle units
	(ii) Chronic full-thickness wound treated with cultured keratinocyte allografts or vapour-permeable membrane	Simulation of an acute wound environment

to healing will be slow, because closure will rely on wound base contraction and edge re-epithelialization. As a consequence, the quality of the scar will tend to 'pathological'.

'Normal'/secondary excisional wound healing (type Ib)

Where surgery requires skin excision, or cutaneous trauma is tangential (e.g. burn injury or friction loss) and the tissue loss is not replaced, then the time to healing and the scar quality will depend on the depth of the loss. Re-epithelialization and restoration of barrier function from adnexal remnants will be slower, the deeper the injury.

Above mid-dermis (type Ibi)

Tangential tissue loss above the mid-dermis leaves a partial-thickness wound that will heal in around one week under ideal circumstances, and result in a 'controllable' scar – as in the surgical split-thickness skin graft donor site. If a traumatic tangential injury clearly reaches the mid-dermis acutely (i.e. a mid-dermal burn injury), then optimal wound management is key to prevent extension of the tissue loss to type Ibii. In extreme Fitzpatrick types, even these type Ibi wounds can scar pathologically.

Below mid-dermis (type Ibii)

Tangential tissue loss below the mid-dermis leaves a partial-thickness wound that will take three weeks or more to heal, and as a consequence will be more liable to chronicity and significant scarring.⁷ It is at this depth, or beyond, that intervention is considered. A full-thickness defect can only re-epithelialize from the wound edge, and will otherwise close substantially by scar contraction of the base.

Abnormal wound healing

Systemic and local factors may reduce the quality of the skin and/or affect wound healing adversely. These are important to recognize and optimize.

Systemic factors

Systemic factors may be congenital or acquired. There are a handful of congenital conditions that affect the processes of healing, and in some instances the clinical quality of the skin and healing. A range of defects in collagen synthesis is seen in Ehlers–Danlos syndrome, and healing is poor.²³ The skin is vulnerable, and healing slow in epidermolysis bullosa, where for example, in the junctional variant, laminin 5 is deficient in the epidermal basement membrane zone.²⁴ The autosomal recessive premature ageing condition progeria manifests many features of normal 'acquired' ageing.²⁵

With age, the changes in healing processes are fairly global, resulting in a delay in wound closure and a reduction in wound strength. How much these changes are the result of increasing comorbidities associated with age, rather than age itself, is not entirely clear. Other acquired systemic factors include: nutrition, drugs, diabetes and smoking. Vitamin C deficiency is the classical example of a nutritional factor involved in wound healing. Although scurvy is not likely with Western diets, vitamin C is an essential cofactor for collagen synthesis. Vitamin A deficiency is also rare in the developed world, but vitamin A can reverse steroid-induced collagenase activity. Zinc is important to many enzyme systems, and deficiency can be seen in large burn injury. In those same injuries, albumin can plummet to around 10 g/L, and although this will delay healing, closure can be achieved.

Obesity is epidemic now in the Western world, and associated with many comorbidities and wound complications following surgery.²⁶ Plastic surgery reconstructions following bariatric surgery are challenging. Large blood vessels will have developed to support the tissue volume, and these may contribute to postoperative bleeding complications. Despite these hypertrophic vessels, tissue perfusion may be poor, and the tissue lymphoedematous and critically colonized. Furthermore, closure after such excisional surgery is by definition under tension, so that infection and dehiscence are more common.

Anti-inflammatory systemic glucocorticoids, non-steroidal anti-inflammatory drugs and chemotherapy drugs globally suppress the cellular responses to wounding. Chemotherapeutic angiogenesis inhibitors, such as bevacizumab, a vascular endothelial growth factor-neutralizing antibody fragment used in colonic cancer, cannot be prescribed six weeks before or after surgery to limit the wound healing risks.²⁷

Diabetes mellitus may affect healing in a variety of complex ways, particularly in the lower limbs. Patients with diabetes are susceptible to atherosclerosis in larger vessels, and tissue oxygen delivery is further reduced by the stiffness of the red blood cells, and the higher oxygen affinity of glycosylated haemoglobin.²⁸ These effects are compounded by any neuropathy, and impaired cellular immunity, phagocytosis and bacterial killing.

Smoking may affect wound healing in both immediate and longer term ways.²⁹ Nicotine causes sympathetic vasoconstriction, and carbon monoxide shifts the oxygen dissociation curve to the left. Long-term smoking accelerates atherosclerotic changes. Smoking appears to be a particular problem in surgery to superficial soft tissue planes, where wide skin undermining with the sacrifice of multiple perforators, and closure under tension are combined, as in abdominoplasty surgery.

Local factors

One of the most controllable local factors for incisional wounds is surgical technique and the handling of tissue. Tissue handling within the specialty can be observed, par excellence, under the microscope during a microvascular anastomosis, where poor

handling results in anastomotic thrombosis.³⁰ Local factors often reflect systemic comorbidities, so that poor blood supply and oxygen delivery, and even critical bacterial colonization are more often than not a local manifestation of a systemic factor. Conversely, the radiotherapy that results in local thromboendarteritis obliterans and causes healing problems over time may also have systemic effects.³¹ In terms of recurrence, radiotherapy is the most effective treatment for keloid scars, damping down the ‘overhealing’ provided it follows extralesional excision directly.³² Breaches in the skin are inevitably colonized by commensals. With time and increasing bacterial number, the body mounts an inflammatory response, and the colonization is termed critical. Critical colonization is not anticipated until around 48 h as a rule of thumb. Once 10^5 organisms are present per gram of tissue, the wound may be considered infected. Chronicity and some level of colonization go hand in hand. Bacterial biofilms are prevalent in chronic wounds, including anaerobic organisms not isolated by standard culture systems, and this is an area of particular current interest in such wounds³³ – and also of course in subcutaneous/cavity wounding and scarring (e.g. breast capsular contracture).³⁴

Mechanotransduction

There is a sense that the skin is constantly subclinically injured to some degree by sheer forces, and indeed even the force of gravity.³⁵ This may drive the baseline turnover of the skin. The effects of physico-mechanical forces on cell behavior, termed *mechanotransduction*, are becoming increasingly recognized and understood in wound healing.³⁶ In 1861, Karl Langer observed that the skin exhibits intrinsic tension,³⁷ and Langer’s lines, defined by the direction in which circular excisional wounds will elongate to ellipses by anatomic site, are used today to orientate excisional surgery. *Tensegrity* describes the way in which mechanical forces regulate biological systems via perturbations in structural architecture; disruption of tensional integrity triggers cellular pathways that restore mechanical homeostasis.³⁸ Cells also actively generate intracellular tension, *cell traction forces*, as they interact with their environment during, for example, migration.³⁹ A cell-centric view of mechanotransduction is, however, inadequate. Conformational changes in the extracellular matrix by mechanical forces can reveal cryptic binding sites and expose growth factors. Non-structural, extracellular, *matricellular* proteins (e.g. connective tissue growth factor) are increasingly implicated in the regulation of healing and scar formation.⁴⁰ Mechanosensing in the skin is a feature not just of fibroblasts but also of keratinocytes and nociceptors. It is quite possible that physical cues during wound healing direct, in part, stem cell fate within that niche.

Any therapeutic effects of silicone gels, pressure garments and linear taping may work through mechanical offloading and mechanotransduction pathways. The use of Botox A to control tension across healing facial scars and improve scar quality is an interesting new approach.⁴¹ Vacuum-assisted closure has become a common approach to complex wound management,

and although poorly understood, must rely to a large extent on mechanotransduction.

TYPE II – NEOCLASSICAL CUTANEOUS WOUND HEALING

‘Supranormal’ healing by skin replacement (type IIa)

Classically, intervention to close a wound was sometimes considered ‘tertiary’ wound healing. The great variety of techniques now available suggest a more structured classification.

Early split-thickness or full-thickness skin grafting of type Ibii (type IIai)

Those tangential traumatic or excisional wounds that are unlikely to heal in a reasonable timescale and are therefore likely to scar are most commonly closed with split-thickness skin autograft. Where the wound is full thickness, the environment optimal and the defect limited in size, a full-thickness autograft will provide a superior reconstruction. Of course, any number of local and distant skin and fasciocutaneous flaps are considered for defects that have resulted in an ungraftable bed, and this category of skin replacement feeds into other classifications of flap reconstruction. Skin and fasciocutaneous free flaps are increasingly being used to close defects in hostile comorbid conditions (e.g. in ‘vasculoplastics’ practice).⁴²

Biotechnological skin replacements (type IIaii)

In recent years, products, often xenograft in nature, have been developed to provide the quality of a full-thickness graft reconstruction from a split-thickness skin graft donor site. ‘Dermal regeneration templates’, such as Integra, engraft to provide a ‘neodermis’ to support a thin autograft in two operative stages.⁴³ A single-stage Integra system has been available following the success of single-stage Matriderm grafting.⁴⁴ Included here also is the system developed by Cuono and colleagues that combines allograft dermis with autologous cultured keratinocytes in the closure of full-thickness burn excision beds.⁴⁵ Cultured keratinocyte technology represents one of the most established forms of somatic stem cell therapy, and sits most coherently within plastic and reconstructive surgery.

‘Supranormal’ healing with apparent acceptance of tissue loss (type IIb)

When tangential tissue loss is accepted and no apparent attempt is made to replace like with like to the level of loss, then there are still interventions that seem to present some clinical advantage. George Winter presented his understanding of tangential wound healing in a porcine partial-thickness

excisional model that included both edge and base contributions to restoration of epidermal barrier function, and introduced the world to the concept of 'moist wound healing'. This spawned a massive industry in moist wound healing dressing systems, initially vapour-permeable membranes.⁴⁶ Although this transformed the 'dry' wound management of the time, it has not proven a panacea, and far more sophisticated biological systems have evolved since (see below). The clinical evidence base for these, however, has been slow to evolve on a cost basis, and so marketplaces have yet to develop around economy of scale.

Type Ibi treated with cultured keratinocyte allograft or biological dressing (type IIbi)

Cultured keratinocyte allografts have been used for decades to accelerate partial-thickness wound healing.⁴⁷ Although they do not survive transplantation long term,⁴⁸ they present a temporary and coordinated 'growth factor factory'. It may also be that they provide a juxtacrine mechanism for 'discontinuous follicle recruitment' by bridging adnexal remnants separated by tangential partial-thickness wounding.¹⁰ Biobrane is a conforming bilayer of porcine collagen and nylon.⁴⁹ It is at least haemostatic and adheres to a clean partial-thickness wound until shed when the epidermal barrier has been restored. The evidence for its efficacy and detail of any mechanism has never been established, but a role for the limitation of colonization of adherence seems likely.

Chronic full-thickness wound treated with cultured keratinocyte allograft or biological dressing (type IIbii)

Chronic full-thickness wounds are a huge financial burden to any healthcare system, and generally associated with comorbidity.⁵⁰ Any comorbid condition should be optimized in the first instance. There then may be some further benefit from cell-based therapy or biological dressings. Both cultured keratinocyte allografts and autografts have been used to treat such wounds.⁵¹ It is suggested that even with poor clinical autograft take, a more acute healing picture is seen, at least clinically – healing is 'kick-started'. The wound bed can be modulated with, for example, hyaluronic acid, an important component of the embryonic extracellular matrix, to improve clinical take, perhaps by supporting a niche-like stem cell environment.⁵²

Fat

There has been a huge recent interest in fat grafting, not only for augmentation including following subcision of indented scars and scar-related fat atrophy, but also to improve healing and the quality of the overlying scar.⁵³ It is fascinating to reflect that Sir Harold Gillies may have used whole-fat grafts in acute closure of

craniofacial traumatic wounds with the same intent many decades ago.⁵⁴ It has been suggested that any effect on healing and scarring results not from the grafted fat directly, much of which is lost, but from stimulation of a local mesenchymal stem cell response. The current controversy is around the method of enrichment of autologous fat to provide safe augmentation long term, and the resolution of this will run parallel with resolution of controversy around any effect on healing and scarring. A recent randomized controlled study in normal human volunteers demonstrated that enrichment of autologous fat with cultured autologous adipose-derived stem cells was significantly more effective, in graft survival terms, than a more standard approach.⁵⁵

Lymphoedema

Lower limb lymphovenous disease is a recognized cause of recurrent cellulitis and chronic wound healing. There is a newly recognized patient base in the morbid obese and postbariatric population, and with the evolution of supra-microsurgical techniques, the promise of new therapies (e.g. lymphovenous anastomosis and lymph node transplantation).⁵⁶

Future

Modern genomic and proteomic techniques allow us to define the processes that control tissue volume and its nature in healing at a molecular level – broadly: migration, proliferation, differentiation and apoptosis. Those techniques require very little material from biopsy, and we should expect to see more evidence from controlled longitudinal human studies available to support our understanding of the different types of healing. The sheer complexity of the pathways and interactions within countless networks will require a systemsomics, or systems biology, approach, calling on applied mathematics and computer modelling. Resources to support controlled human studies of wound healing and interventions are limited in part by a perception that the area is mundane. There are, however, many gaps in our basic understanding of what are quite fundamental processes. Cell-based therapies are expensive, but will continue to offer the most rationale wound management solutions until our understanding is more complete. Longitudinal cost-benefit analyses of novel therapies remain few and far between.

CHAPTER 2

Basic skin flaps and blood supply

Edwin J. Morrison and Wayne A.J. Morrison

O'Brien Institute and Department of Surgery, University of Melbourne, Melbourne, Victoria, Australia

Introduction

Flap surgery is the commonest procedure in plastic surgery and is the essence of the discipline. Critical to its success is an understanding of the soft tissues' blood supply and its compliance and mobility. As all flaps 'rob Peter to pay Paul' it is also about conceptualizing the secondary defect and minimizing its consequences. The art and craft of plastic surgery necessarily requires an aesthetic sense and experience.

Evolution

For almost a century Manchot¹ and Salmon's² detailed studies of the skin's vascular design were overlooked by clinicians. With limited understanding and the simplistic belief that the skin's blood supply was based on a random distribution in the horizontal plane, local flap surgery was unpredictable and its progress curtailed by an adherence to dogmatic rules such as length-to-width ratios and the superiority of proximal over distally based flaps. A generation of surgeons failed to appreciate the simple observation that circumferentially incising large skin lesions in the process of their elevation and removal did not compromise their circulation. The explanation, of course, was that their blood supply was derived from the depths and not horizontally. Surgeons no doubt were aware of the circulation from below but the reality was that sufficient numbers of these vessels had to be divided to permit the flaps to transpose or rotate, and ultimately it was the base fed by the horizontal input that was the critical lifeline. Not until it was shown that flaps could be completely islanded and still live was it possible to move flaps based on these deep vessels. In 1970, Milton elegantly highlighted the fallacy of the length-to-breadth ratio using pig studies to demonstrate the existence of arterialized zones of the integument that would survive over extreme lengths even if completely islanded, provided they retained their arterial source at their base.³ These exciting findings breathed life back into the clinical study of the soft tissue's blood supply. True to

the adage that history is written by the victors, the blind acceptance of random patterns proposed by Harold Gillies⁴ was derived in part from the neglect of the publications of the Dutchman Johannes Esser (1917), Gillies' plastic surgery counterpart for the German army in World War I.⁵ Instead of the complex tube pedicle, Esser performed one-stage 'arterialized biological island flaps' based on the palpable arteries of the head and neck region. He clearly recognized the fundamental concepts of the flap's axial blood supply.

The first clinical application of the new 'axial pattern' concept was the groin flap, based on the superficial circumflex iliac branch of the femoral artery.⁶ The wide arc of rotation of this very long and narrow-based flap of like tissue expanded the single-stage reconstructive options for the regional wounds previously manageable only by multistage transfers requiring protracted immobilization and hospitalization.

What had been anecdotally reported in the early literature and had been empirically adopted in practice, the Indian forehead flap for nasal reconstruction and the epigastric flap in the lower abdomen, now made sense.⁷ The former flap unwittingly captured the supratrochlear/supraorbital vessels and the latter the superficial epigastrics.

With this new awareness, omentum, although not skin, was quickly recognized for its application as an arterialized flap by virtue of it wearing its blood supply on the outside of its surface. The vasculature could be pruned to critical arterial pedicles and tunnelled from the abdominal cavity to cover far-flung defects and then skin grafted.

Other fundamental concepts of skin blood supply were soon elucidated, such as the myocutaneous flap, where the skin relied for its blood supply on vessels perforating through the underlying muscle. Providing the muscle was raised on its blood supply, the overlying skin would survive even when completely islanded. As muscles typically are vascularized often by a single source at their origin, the muscle pedicle added even further length to the arc of flap rotation. The gracilis⁸ and latissimus dorsi myocutaneous flap,⁹ reinventing the earlier findings of Tansini,¹⁰ were the first to be described

and widely adopted. Muscle flaps without skin followed and the anatomical articulation of their vascular basis further expanded the options for one-stage locoregional reconstructions (Figure 2.1).¹¹

Fasciocutaneous flaps recognized for the first time that a significant contribution to skin blood supply was in the plane of the fascia and provided this fascia was included within the flap, large areas of previously unreliably vascularized skin would survive.¹² This particularly applied to the lower limb. Initially they were designed on the assumption their vascularity was in the plane of the fascia and in the limbs flaps were based proximally to capture its source. It was soon clear that much of this fasciocutaneous blood supply derived from perforating branches of named deep vessels emerging vertically between septofascial muscle planes from deep axial vessels, and furthermore these zones could be completely islanded from their proximal connections. Mathes and Nahai have classified fascia and fasciocutaneous flaps into three types: type A, direct cutaneous pedicle; type B, septocutaneous pedicle and type C, musculocutaneous pedicle.¹¹

This led to the unifying concept of angiosome blood supply, where the tissue is considered as a three-dimensional territory or somite structure, akin to vertebrate embryological development, where not only skin but whole mesenchymal somites including skin, muscle and bone have a vascular zone.¹³ This was supported by meticulous cadaver studies and expanded the earlier work of Manchot and Salmon.

Concurrent with this explosion in the understanding of the skin's blood supply, advances were being made in microvascular surgical techniques and instrumentation, initially by the neurosurgeons,¹⁴ but quickly adopted for plastic surgery. These techniques had immediate applications for replantation, but the possibility of transplanting toes and territories of skin by anastomosing specific vessels was now opportune. The

first such flap was an omental transfer to the scalp.¹⁵ Skin flaps soon followed.^{16–18}

Current understanding of the blood supply to skin

Flap surgery involves the transfer of tissue with its vascularity preserved. This requires an understanding of the physiology and anatomy of the integument's blood supply.

Physiology of the skin's blood supply

The blood supply (12.8 mL/100 g/min) to the skin greatly exceeds its metabolic needs because of its homeostatic role in thermoregulation. Perfusion of the skin's capillary beds is regulated by both local and systemic neurohumoral mechanisms. These act on precapillary sphincters and arteriovenous anastomoses, influencing the filling and emptying of the dermal plexuses and in turn not just the circulation of the skin and subcutaneous tissue, but also insensible heat loss and venous return to the heart.

Immediately after elevation of a skin flap, perfusion is transiently reduced by transection of blood vessels, inflammation, a hyperadrenergic state (associated with sympathectomy) and possible reperfusion injury. With no pharmacological means to reliably manipulate these effects at the capillary level, unless the design and execution of a flap includes an adequate circulation to overcome this ischaemic phase the flap may fail.

Anatomy of the skin's blood supply

The circulation of the skin and its underlying structures consists of a three-dimensional continuous vascular network. Conceptually this can be broken into *horizontal* and *vertical* components. Running parallel with the skin, and constituting

Figure 2.1 Mathes and Nahai classification. Patterns of vascular anatomy: type I, one vascular pedicle; type II, dominant pedicle(s) and minor pedicle(s); type III, two dominant pedicles; type IV, segmental vascular pedicles; type V, one dominant pedicle and secondary segmental pedicles. Source: Mathes and Nahai, 1981.¹¹ Reproduced with permission of Lippincott Williams & Wilkins.

the horizontal component of the skin's blood supply are the numerous vascular plexuses (Figure 2.2a). Most important of these are the subdermal plexus and the deeper suprafascial plexus. Where no deep fascia exists, an equivalent structure such as the panniculus carnosus (e.g. platysma, palmaris brevis and the dartos muscles in humans) serves a similar purpose. These are the vascular bases of (random) cutaneous and fascio-cutaneous flaps (Table 2.1).

Vessels arising vertically from their source arteries either *directly* supply the skin, or *indirectly* supply the skin after nourishing deeper structures such as muscle and bone. These are known as 'perforators' and they arise from the deep named vessels, along their axial course, with highest density over the less mobile soft tissue that is adherent to underlying septa. This is particularly evident in the limbs. Perforators anastomose initially with the prefascial plexus before continuing on to the subdermal plexus and are the vascular pedicles on which islands of skin and other soft tissue components may be based (Figure 2.2b). It follows that separate islands of skin and fascia, each based on a separate perforator but ultimately deriving from a common arterial axial vessel, can be raised on this common axis. This permits complex reconstructions with multiple independently oriented flaps.

The blood supply of the skin and its underlying structures can also be divided into vascular territories, or *angiosomes*.¹³ Each territory is connected to its adjacent territory by bidirectional arterioles, the direction being interchangeable and determined by the relative pressure in each territory. The angiosome is the vascular basis for composite flaps.

Drainage of the skin is by a reciprocal three-dimensional venous network of avalvular bidirectional veins with a dominant subdermal component. This in turn drains into large-calibre subcutaneous veins or *venae comitantes* that run with perforators. Superficial lymphatics follow subcutaneous veins and deeper lymphatics follow arteries.

Venous flaps are generally transferred as free microvascular flaps, where the flap is elevated superficially with only the venous system, thereby obtaining a thin flap and reducing morbidity.¹⁹ The flap is arterialized through its veins by anastomosing them to an artery in varying configurations, the tissue being nourished by retrograde perfusion. Understandably, their reliability is inconsistent.

Indications for flaps

Skin defects should ideally be repaired by replacement of what is missing and generally this will include fat as well as skin. In many cases the local laxity of skin will allow direct closure and conversion of the deformity to a linear scar. Sometimes, however, although the wound can be technically closed directly this may create a dish deformity with dog-ears at either end. Removal of these dog-ears only aggravates the underlying problem of missing tissue. Here, well-designed local flaps from redundant areas can redistribute the tension so as to preserve available tissue and restore normal contour.

Defects that cannot be closed directly will need grafting or replacement with flaps. Skin grafts take by engaging with the

Figure 2.2 (a, b) Illustration showing subdermal plexus and suprafascial plexus. Also perforators.

Table 2.1 Classification of flaps based on movement and blood supply

Movement	Blood supply
(a) Local skin flaps	
Advancement	
In-continuity – rare	Random – intact skin base
Islanded (e.g. V–Y)	Random – subcutaneous base
Keystone	Perforator base
Transposition	
In-continuity (e.g. rhomboid, bilobed, Z-plasty)	Random – intact skin base
Islanded (e.g. propeller)	Perforator base
Rotation (e.g. scalp)	Random; arterialized
Combination	
(b) Regional (locoregional) flaps	
Transposition	
Cutaneous (e.g. groin flap, forehead, rhinoplasty, Abbe lip flap)	Subcutaneous arterialized
Muscle/myocutaneous	Arterial pedicle
Fasciocutaneous	Septo(myo)fascial perforators
Neurovascular island flaps (e.g. digits)	Neurovascular A–V pedicles
(c) Distant flaps	
Two-stage pedicle (e.g. cross finger, groin to hand)	Random; arterialized
Multistaged ‘waltzed’ pedicle (e.g. tube pedicle)	Random
(d) Free flaps	
Arterial	Arterial – microvascular anastomosis
Venous	Venous blood supply
(e) Prelamination and prefabrication	
(f) Allotransplantation –	
Opportunistic free flap allograft in patient simultaneously requiring organ transplant (e.g. abdominal wall with bowel transplant)	
(g) Tissue engineering –	
Although prefabricated and prelaminated flaps were the early prototypes of tissue engineered flaps, cell-seeded artificial scaffolds and/or adipogenic matrices are being investigated	Experimental

vasculature of the underlying bed. They are inappropriate in avascular circumstances (exposed bone, tendon, fracture sites, irradiated tissue and mobile beds) and here flaps are required as they possess an independent blood supply. Grafts often contract and may be a poor colour match; where the underlying fatty tissue is missing, they may result in contour defects and adherence to deeper tissues. Apart from burns and extensive injuries where large areas of skin are required it is generally accepted, particularly with the wide range of flap options available, that skin grafts are inferior to flaps and are rarely first choice. Other exceptions include the dorsum of the hand and foot, where thin skin is required. Few flaps meet these needs. Full-thickness skin grafts have an important place on the face, where the tissues are thin with little subcutaneous fat (eyelids, inner canthus,

proximal nose and sometimes nasal tip). Flaps from regions adjacent to these sites are invariably too thick.

Elsewhere, flaps are indicated. Small defects are closed by local flaps from the immediate area and find their greatest expression in the head and neck region, particularly in association with skin cancer resection. Flaps may be in-continuity (transposition, rotation) or islanded (advancement), and their execution defines the quality of the plastic surgeon. Because of their near-perfect tissue match the well-executed local flap may be difficult to spot. Larger defects will require locoregional flaps from a distance and are most likely transposed on their narrow base to maximize their reach (arc of rotation). Because their skin texture, colour and thickness may not match that of the original defect they may require subsequent revisional surgery. Such distant flaps may be fasciocutaneous, myocutaneous or muscle flaps with skin grafts. Composites of tissue may be included – muscle or tendon, fascia or bone – allowing functional reconstruction of complex defects. Their vascular basis will be on the vascular pedicle alone or together with their associated skin, muscle or fascial carrier respectively. Usually the secondary defect will be directly closable.

For very large skin grafts or complex defects where a specialized tissue is needed, such as functional muscle or bone, innervated or hair-bearing skin, free flaps are indicated. These are based on a vascular pedicle and require microvascular anastomosis. Prefabricated (arterialized zone of specialized skin created by the implantation of a vascular pedicle so as to render it transferable as a free flap suitable to match a specific defect) and prelaminated flaps (the neovascularization of composite tissue around a vascular pedicle for subsequent transfer) are more sophisticated free flap indications. Tubed pedicle flaps are now rare but still find applications where there is an absence of recipient vessels at the defect site (Figure 2.3).

Design and application of flaps

Two concurrent considerations are critical to the successful planning of local flaps: (1) blood supply and (2) availability of adjacent mobile tissue (laxity).

Flap design and blood supply

The first consideration in designing a skin flap is to determine whether it will be viable. The vascular limitations on a flap's dimensions are not completely understood, though the principles to follow are helpful. Some flaps in some sites seem more predictable than others, despite the principles, and confidence in local flap surgery comes with trial and error, and ultimately experience with what works and what does not.

The simplest skin flaps are based on the subdermal plexus, the richness of which varies around the body (Figure 2.4). Vague length-to-breadth ratios govern the size of these so-called *random flaps*, with the only certainty being that a flap whose length equals its width will be viable anywhere on the body.

Figure 2.3 Tubed pedicle flaps are largely historic. This patient with osteomyelitis in his leg underwent a tubed pedicle flap from the abdomen using the hand as a carrier. Source: Dr Edwin J. Morrison. Reproduced with permission.

Figure 2.4 (a) Random flap; (b) axial flap; (c) musculocutaneous flap. Source: Dr Edwin J. Morrison, Department of Surgery, University of Melbourne. Reproduced with permission.

Because of the markedly increased vascularity of the face, such flaps can tolerate significantly higher length-to-breadth dimensions.

The area of conventional flaps can be increased by capture of an additional vascular component. Axial flaps, which have a known arterial pedicle coursing along their axis in the superficial plane (e.g. groin flap, forehead flap), may be further enlarged in a random fashion, or by incorporating some of the skin supplied by the next cutaneous perforator in the adjacent angiosome.^{20, 21} Skin flaps elevated with the deep fascia and therefore with the suprafascial plexus intact create a *fasciocutaneous flap*, which can also be elevated with significantly higher length-to-breadth dimensions. Musculocutaneous flaps are yet another variant.

Length-to-breadth ratios of random flaps and the volume of tissue in axial flaps can also be increased by harnessing the *delay phenomenon*. Although its mechanism is incompletely understood, *vascular delay* is a well-established surgical technique capable of improving the vascularity and reliability of a flap prior to its definitive elevation and inset.²² It involves the strategic division of the flap's blood supply so as to deliver a sublethal ischaemic insult. This is postulated to cause vessel dilatation, ischaemic preconditioning and neovascularization. It may also be beneficial in routine flap surgery on high-risk patients who are obese, smokers or who have undergone previous irradiation.

Flaps incorporating the horizontal component of the integument's blood supply are usefully classified as *flaps in-continuity*. For similarly obvious reasons, flaps that are circumferentially incised through dermis or deep fascia (or its equivalent) are *island flaps* whose vascular supply is through perforators (Figure 2.5).

Apart from the native vascularity, caution needs to be taken when flaps are folded to repair complex defects or pass over convex surfaces. Similarly, tight closure when flaps are too small and failure to recognize previous scars in the region may compromise vascularity. Haematoma is perhaps the greatest enemy of local flaps, because of increased tension and the inflammatory toxicity of the underlying blood clot over time.

Figure 2.5 In-contiguity versus island flaps. Source: Daniel & Kerrigan, *Principles and Physiology of Skin Flap Surgery*. In: McCarthy, *Plastic Surgery*. Elsevier, 1990. Reproduced with permission.

Flap design and movement

Having determined that flap tissue is available and that it will be viable, the next question is how it can be moved to cover the defect. Flaps move by way of *transposition*, *rotation* or *advancement* though in reality their movement usually involves some combination of all of these and is often aided by initial partial direct closure of the defect itself.

The first principle of local flap design is to pinch up the skin immediately adjacent to the defect and serially march around its perimeter until the zone of maximally lax skin is detected. It is from this tissue that the flap will be elevated. Because the tissue is lax, it follows that the secondary defect should close directly.

Flaps in-contiguity

Most local flaps are totally elevated from their bed but retain a critical skin base for their vascularity. This especially pertains to transposition and rotation flaps.

Transposition flaps

Lax tissue immediately adjacent to the defect is elevated and transposed, sometimes across intact skin bridges. This creates a secondary defect that is usually closable directly because of the laxity.

The *rhomboid flap* is a particularly useful example of such a flap.²⁴ It is commonly used in skin cancer surgery and the principles can be applied to all transpositions. The anticipated defect is conceived in the form of a rhomboid (unequal parallelogram). A diagonal across the rhomboid is extended the same distance as the length of an adjacent side of the defect into the zone of laxity (a through b to c). A diagonal across the rhomboid is extended the same distance as the length of an adjacent side of the defect

into the zone of laxity ($ac = ce$). A line is then directed backwards from the limit of this point (e) parallel with the side of the defect (ef). The flap thus outlined is elevated and transposed into the defect. Preoperatively if point (f) is estimated to be able to approximate to point (c) then the secondary defect will close (see Figure 30.4a). Selecting the shorter diagonal generally facilitates flap closure because the flap requires less angulation. In some situations the adjacent tissue has not enough laxity to permit closure of the secondary defect and a second flap from the more lax tissue adjacent to this defect will close the tertiary defect (bilobed flap). When flaps are used to cover exposed bone or other non-graftable defects, transposition flaps must be used even if the adjacent zone will not permit direct closure, and here skin grafts are used for the secondary defect (Figure 2.6)

The other common application of the transposition flap is in association with the *Z-plasty*, a fundamental design concept in plastic surgery (Figure 2.7). Z-Plasties are used to release (lengthen) tight or webbed scars, redirect scars into a more favourable alignment and, in combination with linear access incisions, to prevent secondary linear contracture (e.g. Dupuytren disease). The traditional Z-plasty design involves an axial incision along the course of the scar. A back-cut extends from one end of the linear incision into the adjacent tissue at 60° for the same length as the axial incision. A second back-cut the same length is now made on the opposite side of the line, commencing at the other end of the line and directed to the first. This creates an equal-limbed Z incision with its diagonal in the axis of the original scar and flaps at 60° . By interdigitating (transposing) the two flaps created by the design across the midline, the diagonal will now change at right angles to the original

Figure 2.6 The rhomboid flap design, execution and outcome for a temple defect. Note the pinch test and the attempt to position the secondary scar in the natural crease lines of the forehead. Source: Grabb & Smith, 1991.²³ Reproduced with permission of Lippincott, Williams & Wilkins.

axis. This way the scar is partially redirected and, provided the planning is accurate, it should ideally fall within an existing crease line. It is estimated that with a 60° angle transposition the original length of the scar axis will increase by 75% (angle proportional to change in length).

To achieve maximum correction of tight scars it is essential to completely remove the entire underlying scar so that the contracture is fully released. Often it is unrealistic to close 60°

flaps, and smaller angles are required at the expense of lesser lengthening. In fact, when there is not much contracture, the flaps are used to redirect scars rather than increasing length, which is undesirable as it will simply create large redundant dog-ears.

As with all flaps, tissue is borrowed from one place to give to another. Z-Plasties lengthen at the expense of reduction in width. They are no different to other local flaps in that if there is adjacent redundant tissue they work well. This is particularly so

with contracted linear scars where the surrounding tissue is not involved. This tissue has been locked or gathered up in the scar but is not missing, and on release it is available for

transpositioning and scar lengthening. By contrast, where wide scarring has occurred, such as burns, the Z-plasty is essentially cheating by taking tissue from one direction only to create tightness in another. Here, imported skin is needed to replace what is lost either as a graft or more distant flap.

Rotation flaps

These are used in circumstances where there is no differential laxity in the immediate region of the defect. An exaggeratedly large flap is required, extending well beyond the zone of the defect to recruit tissue progressively over a large distance. Rotation flaps are typically employed over the scalp and upper cheek zones. Generally, in designing these flaps it is essential to understand the concept of the pivot point (see below). Their design involves triangulation of the defect, the shortest side being selected as the base (Figure 2.8).

The side of the triangle, which becomes the leading edge of the rotation flap, will advance to meet its opposite side by mobilizing all that tissue beyond the defect sufficient to allow movement. This is achieved by a sweeping curvilinear incision extending from in line of the triangle base over a wide expanse until it encroaches into the zone of laxity. The whole of the large flap is elevated completely up to its base and rotated around its pivot point until the incised edge of the flap rotates forward to close the defect. The base of the flap is that remaining bridge of tissue from the apex of the triangular defect to the point where the flap incision ceases. Most rotation flaps survive on a random blood supply but in the scalp known arterial axes should form the basis of the design and in these circumstances much narrower bases can be conceived.

Because of the spherical shape of the skull, skin flap design will need to accommodate changing lengths and mobility during flap rotation. The secondary defect should close directly by progressive recruitment of tissue along the whole course of the incision or if a back-cut was done to relieve tension on the closure, tissue from the opposite axis should be chosen.

Pivot point

In both transposition and rotation flaps the pivot point is a crucial technical consideration. It always lies at the base of the flap furthestmost from the defect and is the point at which the flap is

Figure 2.7 Z-Plasty.

Figure 2.8 Cheek rotation flap.

Figure 2.9 Pivot point of rotation and transposition flaps.

tethered, preventing further movement (Figure 2.9). Careful planning is necessary to avoid a flap being too small for the defect or becoming ischaemic with closure under tension. A *back-cut* can reposition the pivot point somewhat closer to the defect but comes at the expense of the flap's vascularity. *Planning in reverse* is a useful technique to determine the necessary dimensions of a flap preoperatively.

Advancement flaps

Lax adjacent tissue can be directly advanced into the defect. Realistically, tissue will not advance much more than its capacity for direct closure and to gain real movement requires islanding of the advancement flap. Such flaps then become dependent on subcutaneous or perforator blood supply.

Figure 2.10 (a, b, c, d and e) V-Y flap to upper lip.

Island flaps are mostly advanced into the defect, though in some instances they may be rotated or transposed as in perforator flaps. The classic island flap design is the *V-Y configuration* (Figure 2.10). In general, island flaps tend to be more mobile compared with those in continuity. There are also varying degrees of islanding. Circumferential incision of the dermis alone leaves the deep fascia (or equivalent) intact and in the more mobile parts of the body, such as the face, blunt dissection of the subcutis will usually suffice to achieve the desired amount of movement. Where the overlying skin is more adherent to the deeper structures, as occurs in the limbs and trunk, judicious release of the deep fascia is required. Complete islanding of the suprafascial plexus may not be necessary in every case and a limited release of tethering structures should be trialled initially. A commitment to islanding requires certainty that a perforator lies at the base of the flap.

Finally, consideration needs to be given to the inset of the flap so as to camouflage its outline. To this extent, where possible the flap's axis and its margins should be parallel to crease lines and inset respecting cosmetic units. V-Y advancements along the nasolabial and glabella crease lines expound this concept. A flap design is less conspicuous with straight or gently curving margins than round flaps, as circular lines are unnatural on the face and are instantly recognizable. Respecting this principle it is often better to resect a circular skin tumour as a square rather than simply as a circle. Taken further, consideration can be given to resecting and replacing whole cosmetic units to improve cosmetic outcomes. Well-designed larger flaps are often preferable to circular flaps, which are prone to pin-cushioning as a result of cicatricial contracture. Scars crossing natural crease lines are conspicuous, and across hollows will cause tenting or webbing. A further principle of flap repair is that a single flap cannot realistically repair a defect that transgresses two separate planes (e.g. cheek-alar base). In these cases two flaps from different axes or a flap and a graft will be required.

General principles

Living cells respond to physical and biochemical cues (e.g. hormones, cell–cell signalling molecules and the physical environment) through the extracellular matrix (ECM), which enables adaption to changes in the physiological environment. Regulation of cell function (growth, migration, proliferation and differentiation) is dependent upon contact or adhesion between cells and the substrate (ECM). ECM has three key components: collagen (the structural framework), proteoglycans and adhesive matrix proteins (e.g. fibronectin, vitronectin). Initial contact of cells with a solid substrate is mediated by adsorbed adhesive proteins. Cell surface receptors form bonds with these, leading to cytoskeletal reorganization and progressive spreading of the cell on the substrate. These receptors transduce biochemical signals to the nucleus by activating the same intracellular signalling pathways that are used by growth factor receptors.¹ Next to biochemical cues, mechanical forces play an important role in cell adhesion, growth and possibly differentiation. These responses are mediated through internal cell receptors that respond to mechanical forces. Cell binding to ECM through specific cell–substrate contacts is critical to cell growth control through mechanical forces, resulting in alterations in cell shape and cytoskeletal tension.¹

A biomaterial is a non-pharmaceutical, non-viable material in intimate contact with living tissue used to treat, augment or replace any tissue, organ or function of the body. Ideal properties for a biomaterial include: biocompatibility, non-carcinogenicity, inertness, lack of allergenicity, cost-effectiveness and ease of handling. Biomaterials or tissue engineering scaffolds contain chemical and structural information that may control tissue formation, in a manner similar to cell–cell communication and cell–ECM interaction (Figure 3.1). An appropriate 3D scaffold should facilitate normal cellular organization and behaviour, define and maintain the desired tissue volume, and at the same time promote host integration and implant vascularization.²

Ultimately, the scaffold should undergo non-toxic degradation as it is replaced by the healthy host tissue. Hence, a

biodegradable scaffold is ideally used in tissue engineering. Understanding of the cell–biomaterial interface is important in the choice of scaffold due to a direct impact on cell adhesion – an important step in the survival of anchorage-dependent cells. Both cell proliferation and differentiation can be controlled by functionalization of the biomaterial surface. Multiple studies have shown that the interactions between cells and biomaterials occur at the nanoscale.^{3–5}

With the advent of nanotechnology, nanoparticles are being merged to synthetic scaffolds to develop nanostructured biomaterials and enhance interaction of proteins that control cell adhesion and, thus, tissue formation. Nanocomposites can be defined as multiphase solid materials where one of the phases has a dimension of less than 100 nm. Nanofibrous composite scaffolds are found to decrease immunogenicity, improve the capacity for cell interaction,⁶ and to harbour increased concentrations of fibronectin and vitronectin, the adsorption proteins that reduce apoptosis of transplanted cells.⁷ Biomaterials can be classified as bioinert, bioresorbable or bioactive. A *bioinert* material does not cause any toxic response from the body on implantation and is usually associated with fibrous encapsulation, whereas a *bioresorbable* material undergoes degradation in the body by hydrolysis, enzymes or osteoclasts. *Bioactive* materials produce a biological response from the body that results in a bond between the material and the host tissue. Type and site of biomaterial implantation governs tissue response: hard tissues (bone, enamel and dentin), soft tissues (breast and ocular implants), vascular implants (stents, heart valves and vascular grafts) and connective tissue (cartilage, tendons and ligaments).

A variety of possible scaffold biomaterials are available. Among these are biological polymers (e.g. collagen, elastin, chitosan, silk), biodegradable synthetic polymers (e.g. PGA, PLA, PDLA), synthetic biomimetic compounds (e.g. hydroxyapatite, calcium phosphates), allograft and xenografts, bioactive glasses or combinations of the above. When choosing and designing a biomaterial several factors should be taken into consideration. The most important feature of a biomaterial should be biocompatibility (lack of toxicity to the tissues). In addition, the

Figure 3.1 Cell and biomaterial interactions and factors leading to tissue regeneration.

mechanical properties of a material are important, as they provide structural support, influence cell behaviour, and determine the degree of wear and stress shielding. Geometric variables such as porosity, pore size and pore morphology are also important. A porous scaffold provides a large surface area for neovascularization, nutrient and waste exchange, cell migration and matrix deposition. Scaffolds can be made porous using several different methods. Porogens (i.e. salt or paraffin microspheres) could be incorporated in the polymer and subsequently leached out. Freeze drying of homogenized polymer solvents is another option, in addition to gel casting of organic scaffolds and sol-gel foaming. Surface properties, such as surface topography and chemistry, guide cellular behaviour and control protein adhesion and should be considered as well. In the case that a biodegradable material is chosen for implantation, the rate of resorption should match the speed at which the body replaces the missing tissue and its degradation by-products should be non-toxic. Finally, the biomaterial of choice should be economically viable and conform to the regulatory bodies.

Autologous

The word autologous means ‘related to self’ and refers to tissue that has been derived or transferred from the same organism. Autologous grafts, also referred to as ‘autografts’, can be harvested and transferred from several different tissues in the body (e.g. skin, bone, tendon, cartilage, etc.). The focus of this section is on the autologous transfer of skin, adipose tissue, bone and cartilage.

Skin autografts

From superficial to deep, skin is composed of epidermis, dermis and skin appendages. It has several functions, including physical protection, prevention of fluid loss, protection against ultraviolet radiation, regulation of body temperature, sensation, immunological surveillance and protection from microbiological organisms. Injured skin can heal itself through different phases of wound healing and epithelialization, whereby

epithelium is re-established across a wound. Different phases of wound healing consist of haemostasis, inflammation, proliferation and remodelling, whereas epithelial repair consists of mobilization and migration of epithelial cells, followed by mitosis and differentiation into stratified squamous epithelial cells. If the injury to the skin is grave or the area of skin loss large, this process may take several months and result in significant scarring. In this instance the use of a skin autograft can aid the healing process. Skin graft can either be split or full thickness. Split skin grafts (SSG) contain a variable amount of dermis and can be harvested from several sites (i.e. thigh, buttocks and scalp). The donor site heals through epithelial repair and does not require closure. Full-thickness skin grafts (FTSGs) contain the entire dermis and are usually taken from areas of the body with enough skin laxity to allow direct closure (i.e. groin, forearm, arm, post-auricular and supraclavicular areas).

Skin grafts heal in four phases:

- 1 **Adherence** of the graft to its bed via immediately formed fibrin bonds.
- 2 **Serum imbibition** Skin grafts swell in the first 2–4 days after application due to absorption of fluid.
- 3 **Revascularization** starts on about the 4th day and is a consequence of new vessel formation along new and existing vascular channels in the graft.
- 4 **Remodelling** is the process whereby the histological structure of the graft returns to that of the normal skin.

Skin grafts can fail to ‘take’ for several reasons (e.g. haematoma, infection, excessive shearing, an inappropriate bed, or technical errors such as placing the graft upside down on its bed or allowing it to dry before application).

The main drawback of skin grafts is the fact that they contract. Contraction of grafts is more pronounced with split-thickness skin grafts compared to full-thickness skin grafts.

Adipose tissue autografting

Although autologous fat transfer has gained popularity over the last two decades, Neuber first described the practice, using free autologous fat graft, in the medical literature in the

1890s.⁸ The injectable fat transfer was first described in the 1920s. In the 1950s Peer reported fat grafts losing approximately 45% of their weight and mass per year. He emphasized the importance of a good vascular recipient bed and meticulous haemostasis to ensure optimal graft survival.⁹ Autologous fat transfer can be regarded as the ideal filler. There is no host reaction or carcinogenic response. Being minimally invasive, the procedure is safe and fat is readily available and inexpensive.¹⁰ Limitations include unpredictable and variable rate of absorption, the need for overcorrection and the fact that it involves a surgical procedure. Practitioners must keep up to date with the latest development in harvesting, preparation and application of autologous fat transfer to ensure optimal graft outcome.

Donor site

Currently there is no objective evidence to determine the best donor site for autologous fat harvest. The most common site is the abdomen due to availability and ease of access while the patient lies supine. Other sites include the flanks, extremities (inner thighs, inner knees, inner arms, trochanteric area) and gluteal area. In one study¹¹ the viability of fat cells was analysed *in vitro* by using spectrophotometry from four different anatomical sites: abdomen, medial knee, flank and inner thighs. No difference was found in fat viability 5 h after harvest.

Extraction techniques

Vacuum extraction, syringe aspiration and direct fat excision are well-described techniques in harvesting fat tissue. Although syringe aspiration is the most popular technique, currently there are no objective studies to confirm the benefit of this technique compared to other methods of harvest. However, high negative pressure exerted on adipocytes in conventional liposuction has been reported to cause close to 90% adipocyte rupture.¹² Coleman, who has popularized autologous fat transfer, uses the syringe aspiration technique by using a 3 mm cannula connected to a 10 mL syringe, and aspiration is achieved by manual suction through drawing the plunger.¹³

Infiltration with local anaesthetic agents

Some clinicians do not use any local anaesthetic for fat harvest but most inject the donor site with short-acting local anaesthetic agents with or without adrenaline (epinephrine). A commonly used agent is lidocaine (lignocaine) with concentration dose ranging from 0.5% to 2% and adrenaline ranging from 1 : 80 000 to 1 : 200 000. Coleman recommends using 0.5% lidocaine with 1 : 200 000 adrenaline. A study done by Moore *et al.* on the impact of lidocaine on adipocyte growth in cell culture showed an inhibitory effect on their growth, but cell recovery was displayed by washing cells up to 10 days post exposure.¹⁴ A major clinical advantage of infiltration with local anaesthetic combined with adrenaline is to reduce potential donor site pain, blood loss and bruising.

Preparation

Centrifugation is a popular method of fat graft preparation. The process separates the non-viable components, including blood, oil and lidocaine, leaving behind the adipocyte-rich segment for transfer. Coleman advocates 3 min of centrifugation of aspirated fat at 3000 rpm. This process separates the fat into a bottom layer of tumescent lidocaine and blood, a middle layer of usable fat graft and a top layer of oil from ruptured adipocytes.¹⁵ Other clinicians also advocate the use of centrifugation at different spinning rate and duration,¹⁶ but there is no objective evidence to support which is the best centrifugation method. Rohrich *et al.* have recently challenged the process of centrifugation and found no quantitative difference between the viability of processed and unprocessed fat graft viability¹¹ and Ramon *et al.* using a nude mouse model have demonstrated that fat cell survival after 16 weeks between centrifuged and non-centrifuged fat grafts in terms of weight and volume was the same. Histological analysis showed non-centrifuged fat grafts had less fibrosis.¹⁷

Washing harvested fat grafts as a form of preparation has also been described using lactate Ringer's solution to improve viability.¹⁸ The rationale is to reduce the inflammatory mediators from the graft and minimize an immune response at the recipient site. Currently there is no objective evidence in the literature to suggest washing the harvested fat graft improves overall graft survival.

Application

To maximize graft survival the adipocytes must be in close vicinity to a blood supply. Some suggest that fat placed within 2 mm of an arterial supply will survive and beyond that the risk of necrosis and fibrosis increases.¹⁹ Thus the surface area of fat graft in contact with a vascular recipient bed is essential to improve graft survival. The 'fanning out' technique is one method of injection that ensures deposits of fat graft are spread over a large surface area. Other commonly used injection methods, such as linear threading; serial puncture and cross-hatching techniques, can also be used to achieve the desired outcome. Curved microcannula 2–3 mm in diameter or blunt tip needle 14–19 gauge is commonly used for autologous fat transfer.

Complications

In general, autologous fat transfer is a safe procedure with a low risk profile. However, patients must be warned about bruising, swelling, contour irregularity and infection, along with fat necrosis and calcification. Rare cases of severe complications such as fat embolism of cerebral artery and retinal artery, leading to stroke and blindness, respectively, have been reported in the literature during soft tissue augmentation of the nasolabial fold and periorbital area.^{20,21}

During the consent procedure it is important to cover the common and rare risks of fat transfer along with the limitation of the procedure, which is mainly the unpredictability of the graft take and partial and complete absorption over time.

The rise in popularity of autologous fat transfer in addressing contour deformity and volume restoration over the last few decades has brought this technique under the spotlight. Many questions are still left unanswered on the most optimal donor site, the best method of harvest and preparation. Further objective randomized clinical trials need to be carried out to address these questions. However, this established technique that was first described over 100 years ago is here to stay and serves as a powerful tool in the armamentarium of practitioners in this field.

Bone autografts

The success of bone autografts in the treatment of non-unions is well established. In the tibia, union rates of more than 90% have been reported using iliac crest bone graft at a mechanically stable site.^{22–24} Similar success rates have been documented in the treatment of diaphyseal non-unions.^{25,26} In posterior cervical fusions, success rates in 92% to 100% of the patients have been reported when using autologous iliac bone grafts.²⁷ In addition, bone grafting has been successful in treating recalcitrant^{28,29} and infected^{30,31} non-unions as well as aiding the healing at the docking site of non-unions treated with distraction osteogenesis.³² Over and above the mechanical properties and volume effect, the biologic properties of bone autografts are of great importance.³³

Autologous bone graft continues to represent the gold standard for management of bone defects and non-unions. Bone grafts heal by the following mechanisms: (1) adherence to the surrounding tissue (i.e. incorporation), (2) creeping substitution, also referred to as osseointegration, a process whereby the bone graft acts as a scaffold along which angiogenesis occurs and new bone is formed by progenitor cells, and (3) osseointegration, the differentiation of mesenchymal stem cells into osteocytes. Autologous bone grafts possess biological advantages over allografts and synthetic bone grafts as a result of their excellent combination of osteogenic, osteoinductive and osteoconductive properties.³³

Autologous cancellous bone grafts

The trabecular structure of cancellous bone results in a large surface area. This allows for a high number of cellular components (mesenchymal stem cells and osteoblasts) to be incorporated and explains its excellent osteogenic and osteoinductive properties.³³ Additionally, the trabecular structure allows for easy revascularization and incorporation at the host site.³⁴ On the other hand, one of the limitations of cancellous bone is its poor mechanical properties. The formation of new bone at the site of a necrotic cellular structure weakens the construct within the first weeks. However, increased stability is achieved within months due to the biological capacity of trabecular bone graft to induce new bone formation, once it is incorporated.³⁴

Autologous cortical bone grafts

Cortical bone autografts have a more limited biological profile than cancellous bone autografts. Although cortical bone has fewer osteoblasts, osteocytes and growth factors, and less surface

area per unit weight, the structure of which constitutes a barrier to vascular ingrowth and remodelling, it provides good initial mechanical strength and stability.³⁵ Osteoclastic activity with resorption of the cortices and loss of bone starts at two weeks after the grafting.³⁶ This results in transient weakness with reduction of mechanical strength of up to 75%.³⁷ Experimental studies have shown that cortical grafts have significantly reduced strength at six weeks that remains low through 24 weeks but returns to normal by 48 weeks post implantation.³⁶

Autologous vascularized bone grafts

Autologous vascularized cortical bone grafts have favourable biologic attributes as compared with standard autologous non-vascularized autografts. In addition, they are mechanically superior during the initial 6–12 months after the grafting procedure. Despite their many advantages, their main limitation is that they are more technically difficult to harvest and their implantation requires orthopaedic and microvascular skills. They can also cause significant morbidity at the donor site. Vascularized cortical autografts heal rapidly at the graft-recipient interface as the healing/remodelling process is similar to that of normal bone.³⁴ It has been proposed that more than 90% of the osteocytes may survive the transplantation, if patent vascular anastomoses and stability of the graft are achieved.³⁷ Osteoneogenesis by graft and host can lead to expeditious incorporation of the graft, while the residual weakness of the construct remains minimal.³⁸

As a result of their excellent and cost-effective combination of biologic and mechanical properties, bone grafts continue to be an important tool in the management of bone defects and non-unions.

Cartilage autografts

Cartilage does not possess the regenerative capacity of bone and other connective tissues, due to its lack of vascularity. Cartilage is composed of chondroitin sulfate, a gelatinous ground substance, in which collagen and elastic protein fibres are incorporated. It is flexible, very durable and resistant to compression forces. There are three types of cartilage: hyaline, elastic and fibrocartilage. The most abundant type is hyaline, found in the nose, ear, trachea, larynx, smaller respiratory tracks, costal cartilages and the articular surfaces of synovial joints. It is the precursor to bone in most of the embryonic skeleton. Injury to or congenital deformity of cartilage can result in pain, loss of mobility and significant deformity. The management of moderate to severe cartilage defects has been difficult owing to the lack of its intrinsic ability to self-repair.^{39,40}

Autologous cartilage grafts

Autologous cartilage grafts are commonly used in the reconstruction of congenital ear deformities, augmentation or revision rhinoplasty, and nipple reconstruction post mastectomy. They can be harvested from the costal cartilages, septum of the nose and the ear. Autologous cartilage grafts can provide

excellent results, but are associated with significant donor site morbidity and the final aesthetic result is dependent on the carving skills of the operating surgeon.

When reconstructing injured joint surface cartilage, transplants of osteochondral plugs have become popular because they offer the chance at true hyaline cartilage resurfacing, can be performed in a single procedure using reusable equipment, and do not require outside laboratory assistance. However, osteochondral grafts are not always amenable to arthroscopic technique and may require an arthrotomy. A recent 10-year follow-up study showed superior clinical results of osteochondral grafting compared with microfracture in young athletes with focal osteochondral defects.⁴¹ Disadvantages of osteochondral grafting include limitations on donor site availability and morbidity.⁴² The space between cylindrical grafts may impair the quality of the repair as poor integration of full-thickness gaps were shown in experiments in goats.⁴³

Autologous chondrocyte implantation

Autologous chondrocyte implantation (ACI) aims to provide hyaline cartilage for repair of injured articular cartilage. Over the last 20 years, it has gained significant popularity. This cell-based technique takes place in three stages: (1) 200–300 mg cartilage is harvested arthroscopically from a less weight-bearing area (intercondylar notch, superior ridge of the femoral condyles). Chondrocytes are isolated after enzymatic removal of the matrix, grown *in vitro* for 4–6 weeks, and then applied to the damaged areas as the patient undergoes a second procedure.

A clinical study of ACI showed an improvement in symptoms in 14 out of 16 patients with femoral condylar lesions at 2 years follow-up.⁴⁴ Another study with a 2- to 9-year follow-up showed good to excellent clinical results following ACI, especially in patients with isolated femoral condyle lesions and osteochondritis dissecans.⁴⁵ At 10–20 years after ACI, 74% of 224 patients reported improvements in symptoms.⁴⁶ Equivalently, matrix-induced ACI resulted in good to excellent clinical outcomes in 12 out of 14 patients after 2- to 8-year follow-up. On the other hand, in a 5-year long-term randomized controlled clinical trial, ACI results were comparable to those of microfracture. Subgroup analysis showed that patients with a time of symptom onset of less than 3 years had better outcomes with ACI than with microfracture.⁴⁷ ACI is technically more challenging, with high reoperation rates of 9–20% and is associated with higher costs.⁴⁸ It also requires *in vitro* expansion of chondrocytes, which theoretically increases the chance of introducing infection, is dependent upon an outside lab, is very expensive, requires an arthrotomy, and necessitates two operations, typically at an interval of two weeks.

Allografts and xenografts

Allografts can be defined as graft of tissue obtained from a donor of the same species as, but with a different genetic make-up from, the recipient. In recent years natural ECM have been

procured, processed and marketed for clinical use as patches to reinforce tissue repair. ECM may provide temporary mechanical support with inherent biological properties that can influence host cell attachment, proliferation and differentiation and ultimately integration into the host tissue.

Bone allografts

Bone allografts can be applied to aid healing of the bone injured either by trauma or due to iatrogenic causes. Survival of bone grafts depends on systemic factors that also affect wound healing (e.g. age, nutritional stage, immunosuppression, diabetes, obesity). In addition, bone grafts placed in an orthotopic position are less prone to absorption. Scarring and infection and previous radiotherapy at the site of the recipient bed also adversely affect graft survival. Allografts lose some of their biologic properties through sterilization and synthetic bone substitutes have only osteoconductive properties if not combined with human growth factors or autograft. If heterologous or synthetic bone is combined with growth factors, these composite grafts may have equal biologic properties to autologous bone grafts, but further research is required to determine their efficacy and cost-effectiveness.

Fascia allografts

An engineered fascia device may be applicable for ligament repair, extension of rotational muscle transfers, grafting lacerated muscles, periosteal coverage, correction of eyelid ptosis and wound healing. Fascia lata or fascia from the iliotibial tract is most commonly used as allografts. An *in vitro* study comparing the histological features, tensile strength to failure, creep and stress-relaxation properties of allograft iliotibial bands with those of tibialis anterior tendons and anterior cruciate ligaments showed they shared a similar structure made of aligned collagen fibres.⁴⁹

No significant difference was observed between allograft iliotibial bands and tibialis anterior tendon ultimate tensile strength, creep and stress-relaxation viscoelastic properties. Anterior cruciate ligament tensile strength was shown to be lower than that of the other two alternatives, although during creep and stress-relaxation testing it was shown to be superior. Allograft iliotibial bands showed low cytotoxicity and good biocompatibility *in vitro*, with a somewhat higher propensity to favour cell attachment and infiltration over time. A clinical study using banked fascia lata allografts for abdominal wall defects showed there were no major signs of recurrence, laxity, infection of grafts or other related pathologic symptoms.⁵⁰ Neofascial tissue appeared stable until 3–6 months, later being gradually degraded and replaced by the host tissue.

Lyophilized or freeze-dried fasciae share similar characteristics of the other alloplastic materials and have several advantages: biocompatibility, ability to be replaced by the host tissue, good mechanical properties and ease of handling.⁵¹ Although lyophilized dura and autogenous fascia have been used for similar purposes, dura has been reported to cause Creutzfeldt-Jakob disease. The major concern with stored fascia is that it is

prone to resorption (up to 10%). In a report, it was pointed out that fascia resorbed in 14 of 127 cases observed for a four-month period.⁵¹

Dermal matrices

Integra

Integra® (Integra LifeSciences Corp., Plainsboro, NJ, USA) is a dermal regeneration matrix consisting of bovine collagen, chondroitin-6-sulfate and a silastic membrane. It has gained widespread use in the clinical treatment of deep partial-thickness and full-thickness burn wounds, full-thickness skin defects, chronic wounds and in soft tissue defects.^{52–55} The bovine collagen dermal component integrates with the patient's cells and the temporary epidermal silicone is peeled away as the dermis regenerates. A very thin autograft is then grafted onto the neodermis.^{53,56}

Heimbach *et al.* showed that Integra was superior to autograft, allograft or xenograft in terms of wound healing time.⁵⁵ However, with regard to wound infection and graft take, Integra did not produce as good a result.^{55,57} Soft tissue coverage with Integra has been successfully used in reconstructive and burn surgery to increase the thickness of the resulting skin and to cover underlying structures like bone or tendon.⁵⁸ However, it requires a two-stage procedure before final defect coverage to allow for adequate vascularization of the template.⁵⁹ Integra provides an immediate donor site coverage independent of wound size.⁶⁰ Additionally, it creates a gliding surface between the underlying structures (e.g. paratenon or nerves and the split-thickness skin graft). Long-term outcomes regarding functionality and cosmesis after radial forearm flap donor site coverage with Integra and split-thickness skin show aesthetic and functionally successful defect coverage.⁶¹

AlloDerm

AlloDerm® (LifeCell Corporation, Branchburg, NJ, USA) is fabricated by a decellularizing cadaveric skin. After processing, the skin is reduced to a basement membrane and properly oriented dermal collagen matrix that theoretically will not be rejected. It ultimately transitions into the host tissue. It has been used extensively in patients with burns to provide biological coverage of third-degree burns and as a framework for split-thickness skin grafts^{62,63} and for intraoral resurfacing after tumour excision.⁶⁴ AlloDerm has been shown in clinical trials to be well tolerated. It becomes integrated into the host skin, is invaded by fibroblasts, and undergoes neovascularization and neoepithelialization, without any evidence of rejection or adverse reaction to the implant by the patient.

Its ability to support neovascularization and tissue ingrowth permits persistent volume correction. This gives AlloDerm an advantage over other injectable forms of collagen. A significant drawback of AlloDerm sheets is the requirement of an incision for placement. An injectable form of AlloDerm (Micronized AlloDerm) has been created by homogenizing AlloDerm sheets

cut into strips. The product is injectable-sized particles of AlloDerm that maintain the ultrastructure of the dermis and can pass easily through a 26-gauge needle.

Several large published series of patients undergoing breast reconstruction utilizing acellular dermal matrices have reported very low rates of capsular contracture.⁶⁵ In addition, a primate study reported the absence of capsule around implants where human acellular dermal matrix was placed.⁶⁶ The absence of a capsule has been observed clinically at the time of implant exchange and was recently confirmed histologically in a clinical study where biopsies were obtained at the time of implant exchange.

Strattice

Strattice™ (LifeCell Corporation, Branchburg, NJ, USA) is an acellular reconstructive tissue matrix derived from porcine dermis, which undergoes proprietary processing that removes cells and significantly reduces the risk of xenogeneic rejection response. The presence of the α -Gal epitope on porcine tissues has been associated with rapid rejection. The enzymatic processing of Strattice significantly reduces the amount of α -Gal epitope in the absence of damage to the matrix integrity (collagen and elastin architecture).⁶⁷ In addition, glycosaminoglycans are still present, indicating that Strattice retains key markers for the presence of relevant biochemical components. The tissue matrix is provided in two forms – pliable and firm. Performance of Strattice has been evaluated by implantation into the abdominal wall of a primate excisional repair model. The animals tolerated the implants well and exhibited no clinical signs of inflammation, laxity, hernia or visceral tissue adhesion. Histological evaluation revealed marked host fibroblast repopulation and neoangiogenesis as early as two weeks post implantation, reaching a plateau at three months. Immunological evaluation of immune cell infiltration demonstrated an early mixed cellular inflammatory response at two weeks, which was transient and diminished to baseline levels by three months. A study comparing three non-cross-linked, commercially available ECM scaffolds (Strattice, Veritas and XenMatrix) showed that the intrinsic denaturation temperature for Strattice, Veritas and XenMatrix was 51°C, 38°C and 44°C, respectively. In addition, the susceptibility to collagenase degradation was increased in Veritas and XenMatrix. These findings suggest more ECM modifications in the Veritas and XenMatrix scaffolds.⁶⁸ In an *in vivo* primate model, Strattice permitted cell repopulation and was remodelled over six months. Veritas was unstable at body temperature, absorbed rapidly and associated with moderate inflammation. XenMatrix caused severe inflammation.⁶⁸

The use of Strattice for repair of incisional hernias in Yucatan pigs compared to primary closure showed that primary closure caused more scarring and bone hyperplasia along the incision line. Strattice elastic modulus and tensile stress were similar to fascia and it provided a more complete wound healing response compared with primary closure.⁶⁹

Clinically, Strattice may enhance soft-tissue support in patients with poor-quality mammary soft-tissue support, especially in implant-based breast reconstruction post mastectomy and in certain patients undergoing augmentation mammoplasty. It has been associated with reduced implant-related complications, including capsular contracture, rippling, palpability and malposition.⁷⁰

Alloplastic

Metals

An ideal metal implant is resistant to corrosion, has a high strength and is biocompatible. Advantages of metallic biomaterials include lack of donor site morbidity and availability. Disadvantages include eliciting host reaction to the material, and their high cost. Metals are used in osteotomy/fracture fixation (plates, screws and wires), cranial plates and artificial joints. Most metals used as biomaterials are alloys. An alloy is a mixture of two or more metals in a single material. Commonly used alloys include stainless steel and alloys incorporating cobalt, titanium or gold.

Stainless steel

Stainless steel is an alloy composed mainly of iron, chromium and nickel. It is highly corrosion resistant in the physiological environment compared to other formulations. Chromium forms a strong adherent surface oxide layer thus rendering it resistant to corrosion. Despite the favourable anticorrosive properties of stainless steel, the leaching of metallic ions can lead to inflammatory reactions in the surrounding tissues and may cause pain.

Cobalt alloys

Vitallium is an example of a cobalt alloy composed of cobalt, chromium and molybdenum (Co–Cr–Mo). This alloy has similar strength to stainless steel but is lighter and less resistant to corrosion.⁷¹

Titanium (Ti)

Titanium is highly resistant to corrosion and has excellent biocompatibility. It has the capacity to form direct chemical bonds with mineralized bone matrix, leading to osseointegration⁷² and providing high stability of these implants. Osseointegration allows for a solid incorporation between the soft tissue, implant and bone. Osseointegrated percutaneous implants have a wide application in plastic surgery, particularly in prosthetic reconstruction. In the first stage the titanium implant is placed into bone and covered by periosteum or bone for at least three months. Titanium has a unique property in that it forms direct chemical bonds with mineralized bone matrix. The histological appearance shows calcified matrix in direct apposition to the metal surface without intervening fibrous tissue. It is this interaction that provides unparalleled stability for titanium implants.

At the second stage the implant is uncovered and a permanent prosthesis is made for the fixation to the implant. Maxillofacial prosthetics largely rely on the support of titanium osseointegrated implants.

Combined with aluminium and vanadium alloy, titanium becomes less malleable. There is also less scatter artefact on radiographic images compared to cobalt alloys and stainless steel.⁷³ Titanium mesh is used in orbital floor reconstruction and for calvarial reconstruction in cranioplasty. Titanium microplates are routinely used for bony internal fixation.

Gold (Au)

Gold has limited application in plastic surgery. Although resistant to corrosion, gold lacks the appropriate mechanical properties and is costly. It still has a role in facial palsy patients by creating iatrogenic ptosis through gold lid loads in the upper eyelid and addressing lagophthalmos.

Ceramics

Ceramics are solid materials composed of inorganic non-metallic substances. Ceramic materials may be amorphous or crystalline. In 1969 L.L. Hench discovered that various kinds of glasses and ceramics could bond to living bone.

They are excellent heat and electric insulators and are heat and corrosion resistant. In addition, they are hard and brittle (fracture without deformation), strong in compression, but weak in shearing and tension. Examples of ceramic materials are porcelain, cements, pottery and glass (amorphous). Chemically, ceramics are normally formed by a hybrid of covalent and ionic bonds and the atomic repeating order can be short range (e.g. glass) or long order (e.g. crystals). The advantages of ceramics are that they can be chemically inert in many environments or designed to be bioactive in the body. They have high wear resistance, high modulus (stiffness) and compressive strength. They are aesthetic and can be used for dental applications. Their composition can be similar to the mineral component in bone. Their disadvantages are brittleness (low fracture resistance, flaw tolerance), low tensile strength (with the exception of fibres) and poor fatigue resistance.

Bioinert ceramics

Bioinert ceramics include oxide ceramics (Al_2O_3 , ZrO_2), silica ceramics, carbon fibre and synthetic diamond. Alumina (Al_2O_3) and zirconia (ZrO_2) are the two most commonly used structural bioceramics. They are primarily used as modular heads on femoral stem hip components, but can also be used for dental restorations – crowns, bridges, brackets. They have the tendency to wear less than metal components, and the wear particles are generally better tolerated. In addition, they have good mechanical and aesthetic properties.

Bioactive ceramics

Bioactive ceramics include tricalcium phosphates, synthetic hydroxyapatite substitutes and bioactive glass (e.g. 45S5 Bioglass®). Bioactive glasses are osteoproliferative and encourage

Figure 3.2 Hydroxyapatite (HA).

Figure 3.3 Tricalcium phosphate.

bone cells to produce matrix. They bond to soft tissue and hard tissue and are known to stimulate genes in osteoblasts. Bioglass (composition =46.1% SiO₂, 24.4% NaO, 26.9% CaO, 2.6% P₂O₅ (mol%)) was the first material seen to form an interfacial bond with the host tissue. The strength of the bond between Bioglass and cortical bone was shown to be similar to the strength of the host bone.⁷⁴ Bioglass particulate has been in clinical use since 1993 as Perioglas®, used to fill periodontal defects. Hydroxyapatite (HA) and tricalcium phosphate are the most commonly used ceramics in plastic surgery. HA is a naturally occurring mineral form of calcium apatite. It is the hydroxyl end part of the apatite group. Carbonated calcium-deficient HA is the main mineral of which dental enamel and dentin are constituted. By a hydrothermal exchange process of carbonate for phosphate it becomes identical to bone. The material comes as blocks or granules and can bond with adjacent bone without an inflammatory response. It provides a scaffold for bony ingrowth and is not resorbed (Figure 3.2).

Tricalcium phosphate is a synthetic material, more porous than HA and prone to resorption. Its porosity ranges from 30% to 80%. It is usually supplied in blocks or granules, similar to HA (Figure 3.3). Calcium phosphate cement is a synthetic HA cement that when mixed with water and a drying agent (sodium phosphate) forms a paste that hardens to form a microporous HA.⁷⁵ The cement improves contour adaptability and eliminates the need for prefabrication. It is used in calvarial and chest wall defects. It is biocompatible and associated with minimal reabsorption and inflammatory response.⁷⁶

Polymers

Polymers are long-chained molecules composed of small repeating units. Synthetic polymers are found in facial implants, breast prosthesis, sutures, implantable fabrics and joint replacements.

Silicone

Silicon (Si) is a semi-metallic element found abundantly in nature as various forms of silicon dioxide (silica) or silicates. Silicones are mixed inorganic-organic polymerized siloxanes. The basic repeating unit of silicone polymers is siloxane [R₂SiO]_n, where R is an organic group such as methyl, ethyl or

Figure 3.4 Poly(dimethylsiloxane) (PDMS).

Ethylene

↓ Polymerization

Or more simply

Polyethylene

n = a very large integer

Figure 3.5 Polyethylene.

phenyl. The most commonly used formulation of silicone in medicine is poly(dimethylsiloxane) (PDMS) (Figure 3.4). Medical silicone is available as a liquid, gel or rubber by altering the length and cross-linking of the PDMS chains.⁷⁷

Medical grade silicone is biocompatible, non-allergenic and non-absorbable, which has led to many medical applications including catheters, shunts and intraocular lenses. In plastic surgery, silicone implants have been used in craniofacial surgery for malar and chin augmentation. In hand surgery, silicone rods are routinely used for two-stage tendon reconstruction and as spacers for arthroplasty.

In breast surgery, silicone has been used as prosthesis since 1963. It is estimated that over 2 million women worldwide have received silicone gel-filled implants. Among a variety of biomaterials available, silicone seems to have become the favoured option, especially in adipose tissue replenishment and small joint replacements. It was first introduced as a relatively inert biomaterial, thought to cause minimal inflammation. However, long-term studies are now revealing that silicone affects wound healing and causes capsule formation as a foreign body reaction. Capsular contraction of silicone implants can lead to pain, distortion and hardness. Although alternatives, such as porous polyurethane implants, allow better tissue fixation and are reported to reduce the incidence of capsule formation, they feel unnatural and there is a perceived risk of carcinogenesis. It is true that silicone is relatively inert, however, its tendency to fragment into miniscule particles limits its interfacial biocompatibility, and this holds true for polyurethanes as well. If subjected to repetitive loading and deformation silicone can

Figure 3.6 Poly(aryl-ether-ether-ketone) (PEEK).

fragment into small particles, leading to silicone granulomas caused by a reaction of the immune system.

On the other hand, the fibrous capsule that forms around the implant helps to keep the implant in position and makes subsequent removal easier. There is no evidence that silicone implants are associated with any major diseases, such as connective tissue disorders, cancer or neurological disorders. Silicone breast augmentation is not a contraindication to breastfeeding.⁷⁸

Polyethylene

Polyethylene is the simplest carbon polymer ($-C_2H_2-$) composed of a carbon backbone (Figure 3.5). Pore sizes range from 100–250 μm , which allows tissue ingrowth and stabilization of the implant. In plastic surgery, high-density polyethylene (HDPE) (Medpore[®]) is used for its biocompatibility and tensile strength. The material is porous, allows tissue ingrowth, and is commonly used in ear reconstruction, facial and cranial augmentation. It is available in sheets and blocks that can be sculpted intra-operatively. The host forms a thin capsule around the material with overall low infection rates,⁷⁹ although extrusion is an infrequent problem. Polyethylene can be modified by adding a methyl group to each monomer to form poly(1-methylethylene) or polypropylene (Prolene[®]). This material is commonly used as a non-absorbable suture and can be woven into a fabric mesh, used for chest wall, pelvic floor and abdominal wall reconstruction.

Replacement of the hydrogen atoms in polyethylene with fluorine yields polytetrafluoroethylene (PTFE, Teflon[®]). This material is known for its non-stick properties and good biocompatibility. Rapidly stretching PTFE under certain manufacturing conditions results in formation of a strong microporous material known as expanded PTFE (ePTFE, Gortex[®]). The micropores allow ingrowth of soft tissue and stability of the implant. It has been used as vascular graft since the 1970s and also in the chest wall, abdominal and pelvic floor reconstruction.⁸⁰ The drawback of PTFE vascular grafts is the high incidence of stenosis when small in calibre.

PEEK

Poly(aryl-ether-ether-ketone) or PEEK is a relatively new family of high-temperature thermoplastic polymers, consisting of an aromatic backbone molecular chain, interconnected by ketone and ether functional groups. The chemical structure of polyaromatic ketones confers resistance to chemical and radiation damage, biocompatibility, inertness and radiolucency.⁸¹ The material has been gaining greater popularity over time for its

Figure 3.7 PEEK implant applied in cranial vault reconstruction.

medical application. PEEK is being used in facial and cranial reconstruction and its application extends to the field of plastic surgery. It has similar mechanical properties to native bone and is biostable. As a radiolucent material it produces minimal artefacts during imaging (Figures 3.6 and 3.7).

Conclusion

Many alternative biomaterials are available for the practising surgeon; all have their specific benefits and limitations. They have become increasingly popular over the years for their long 'shelf life', ease of use, safety and availability.

CHAPTER 4

Local anaesthetics

Yasamin Ziabari

The Central London School of Anaesthesia, Royal Free Hospital, London, UK

Introduction

Local anaesthetic agents cause reversible blockade of the neuronal sodium (Na^+) channel, thereby blocking transmission of nerve impulses from nociceptive afferents.

Mechanism of action of local anaesthetics

In the unionized state, local anaesthetics are varying lipid soluble, thereby penetrating the phospholipid cell membrane into the axoplasm. Here, re-ionization of the molecule takes place. It is this re-ionized molecule that then enters and blocks sodium channels, preventing sodium influx into the neuron during depolarization, and thus halting propagation of an action potential.¹

Local anaesthetics have also been shown to exert far-reaching effects on other receptors, independent of their action on sodium channels. These include inhibition of the local tissue inflammation that results in nociceptor sensitization, leading to pain and hyperalgesia.² They may also be involved in priming of descending inhibitory pain pathways, which could show clinical benefit in the reduction of neuropathic pain.³ Furthermore, local anaesthetics have been shown to have antithrombotic, antimicrobial and neuroprotective actions.^{4,5}

Nerve fibre characteristics and differential blockade

Several nerve fibre characteristics have been shown, *in vitro*, to govern the sensitivity of nerve fibres to local anaesthetics:⁶

- Smaller nerve fibres with shorter axons are more easily blocked compared to larger nerve fibres with longer axons.
- Smaller diameter nerve fibres (e.g. 0.4–1.2 μm C-fibres which transmit pain, temperature and touch) are blocked at lower concentrations compared to larger diameter nerve fibres.
- Myelinated fibres (e.g. A- α fibres, which convey motor and proprioception) are more easily blocked than unmyelinated nerve fibres (e.g. C-fibres), as local anaesthetic tends to pool within the myelin sheath.

These principles do not, however, consistently correlate with the clinical observations. When blocking peripheral nerves, there is usually an order in the disappearance of sensing modalities: pain, temperature, deep pressure and finally motor function loss.

Physiochemical properties of local anaesthetics

Chemistry

Local anaesthetics are weak bases.¹ Their basic molecular structure comprises a lipophilic aromatic moiety and a hydrophilic amino domain (Figure 4.1).

Depending on the chemical linkage between the respective lipophilic and hydrophilic groups, local anaesthetics can be classified as either amides or esters. This linkage has implications on drug metabolism and allergenicity (Table 4.1).

Potency

The potency of local anaesthetics correlates well with lipid solubility and molecular weight *in vitro*.⁸

Other factors affecting potency include tissue distribution and direct vasodilator actions of the local anaesthetic.

Duration of action

Local anaesthetics are classed as 'short', 'medium' or 'long' acting. The duration of action positively correlates with the degree of protein binding: the more protein bound a local anaesthetic, the longer the duration of action, with the 'unbound' portion of the drug being biologically active.⁸ However, local anaesthetic molecules remain bound to sodium channels for seconds only. Given such a high dissociation rate, of greater relevance are factors that maintain a high concentration of local anaesthetic molecules around the nerve. These factors are:

- local anaesthetic lipid solubility (there is a direct correlation between lipid solubility and protein binding);
- tissue vascularity (depends on regional blood flow, and the addition of vasoconstrictors); and
- the intrinsic vasodilatory properties of local anaesthetics.

Local anaesthetics cause vasoconstriction at very low concentrations and vasodilatation at higher, clinically useful, concentrations.¹ Considerable variability exists however. Moreover, ester local anaesthetics are more potent vasodilators compared to amides. The exception to this rule is cocaine, which causes vasoconstriction by blocking reuptake of noradrenaline (nor-epinephrine) at sympathetic nerve endings. The greater the intrinsic vasodilatory action of a local anaesthetic, the more pronounced the effect of the addition of vasoconstrictors.

Onset of action

The faster the diffusion of local anaesthetic across a nerve sheath, the faster the onset of action. The rate of diffusion is determined by:

- the site of local anaesthetic injection,
- the concentration of local anaesthetic used,
- the degree of ionization of local anaesthetic molecules.

The latter is related to a physiochemical property of a drug known as the pK_a . The pK_a is the pH at which 50% of the drug is present in an ionized form.¹ For basic drugs, such as local anaesthetics, a greater proportion of drug is present in the ionized form at a pH below the pK_a ; at a pH above the pK_a , a greater proportion of the drug will be unionized. The reverse is true for

weak acids. Therefore, local anaesthetics with a higher pK_a will have a greater drug fraction present in the ionized state, resulting in a slow onset of action.¹ The most clinically relevant comparison is the faster action onset of lidocaine (lignocaine) (pK_a 7.9) compared to bupivacaine (pK_a 8.1).

Pharmacokinetics of local anaesthetics

Absorption

Absorption of local anaesthetics depends primarily on:

- the site of injection,
- the addition of vasoconstrictors, and
- the physiochemical properties of the local anaesthetic agent itself.

On reaching the systemic circulation, local anaesthetics are taken up by distant organs according to vascular density.⁹ Highly vascular organs, such as the brain, heart, lung, liver and kidneys, will have greatest exposure to the peak concentration of unmetabolized local anaesthetic. Uptake is determined by the tissue–plasma partition coefficient.

Distribution

Local anaesthetic molecules can be ‘free’ or bound to plasma proteins. Alpha-1 acid glycoprotein binds the weakly basic local anaesthetic molecules with high affinity. However, albumin represents a greater fraction of plasma proteins, and as such has a high capacity (but comparatively low affinity) for binding to local anaesthetic molecules. Local anaesthetic protein binding is pH-dependent, and decreases as the pH decreases.⁹ This has important clinical relevance. For example, in local anaesthetic systemic toxicity (see below), a metabolic acidosis may ensue secondary to tissue hypoxia. Thus as the plasma pH decreases, the proportion of ‘free’ drug increases, potentiating the toxicity. Furthermore, intracellular acidosis increases conversion of the local anaesthetic molecule into the cationic state, rendering the molecule unable to cross the cell membrane. This ‘ion trapping’ exacerbates the toxicity further.

Figure 4.1 Chemical structure of a local anaesthetic.

Table 4.1 A comparison of the main characteristic differences between amide and ester local anaesthetics

Class	Examples	Allergenicity ^a	Pharmacokinetics	Stability
Amides	Lidocaine Mepivacaine Bupivacaine Ropivacaine Levobupivacaine	Rare ⁷	Extensively protein bound Hepatic metabolism by amidases; slower than ester metabolism thus potential for accumulation	Long shelf-life and heat-insensitive unless mixed with glucose
Esters	Procaine 2-Chloroprocaine Tetracaine (Amethocaine) Benzocaine Cocaine	Rare, but more common than with amides, especially with procaine Cross-reactivity may exist with other esters Implicated metabolite: <i>p</i> - aminobenzoic acid	Minimally protein bound Hydrolysis by plasma cholinesterase and other esterases	Short shelf-life due to spontaneous hydrolysis

^aAntioxidant additives, or preservatives such as metabisulfite or parabens may be implicated in causing non-anaphylactic reactions.

Clearance and metabolism

Esters (except cocaine) undergo rapid hydrolysis by plasma cholinesterases, and other non-specific esterases.¹ Their metabolites are inactive, but may be associated with hypersensitivity reactions. Amides are metabolized in the liver by the action of amidases.¹

Hepatic clearance is dependent on the hepatic blood flow, and the hepatic extraction ratio, which depends on the ratio of unbound to protein-bound drug. Drugs that are comparatively less protein bound (e.g. lidocaine) have a higher hepatic extraction ratio.¹⁰ Clearance is thus only limited by hepatic blood flow. Thus factors reducing hepatic blood flow (e.g. heart failure) may increase toxicity. Conversely, the clearance of drugs that are more protein bound (e.g. bupivacaine) is more dependent on free drug concentration, rather than hepatic blood flow.⁹ Intrinsic liver disease may, in turn, affect free drug concentration (e.g. a reduction in liver enzymes or reduced plasma protein production).

Patients with liver disease and cardiac disease can receive 'normal dose' single shot blocks. However, catheter infusions or repeated blocks should be given at a reduced dose.¹¹

Renal failure associated with severe uraemia can be associated with reduced clearance and more rapid absorption of local anaesthetic, leading to higher peak plasma concentrations.

Some local anaesthetics may undergo first-pass metabolism by lung extraction due to the lower pH of the lungs compared to the plasma, resulting in an 'ion trapping' effect. This effect is lost in patients with right-to-left cardiac shunts, thus increasing the risk of toxicity.¹²

Local anaesthetics in clinical practice

Table 4.2 summarizes the pharmacokinetic and pharmacodynamic properties of the most commonly used local anaesthetics.

Concentration of local anaesthetics

A 1% solution of a drug contains 1000 mg of drug per 100 mL of solution. Thus a 1% solution of lidocaine contains 1000 mg of lidocaine per 100 mL (10 mg/mL). Similarly, a 0.5% solution of bupivacaine contains 500 mg of bupivacaine in 100 mL of solution (5 mg/mL).

Clinically useful adjuncts

Vasoconstrictors

Adrenaline (epinephrine) is the most commonly used vasopressor. It slows the rate of absorption of local anaesthetics, thereby prolonging the duration of action¹¹ and reducing the risk of toxicity. Furthermore, it can help decrease surgical blood loss, and may identify inadvertent intravascular injection. Absolute contraindications to use include injection close to tissues with inadequate collateral circulation (ankle, wrists,

digits and penis) and intravenous regional anaesthesia. Relative contraindications to use include the presence or risk of tissue ischaemia, cardiac disease, hypertension and concomitant use of other sympathomimetic drugs (e.g. tricyclic antidepressants).

The maximum safe dose of adrenaline is 4 µg/kg; concentrations in excess of 1 : 200 000 should not be used (Table 4.3).

Sodium bicarbonate

Sodium bicarbonate (NaHCO₃) raises the pH of the local anaesthetic solution, thus increasing the fraction of unionized drug able to traverse the neuronal membrane.¹¹ It may also reduce the pain of injection.¹³ Furthermore, the speed of onset of the local anaesthetic is theoretically increased. However, the rise in pH seen is only modest, and limited by the solubility of the base form of the drug. This translates to only modest decreases in block onset time.¹⁴

The recommended dose is 1 mL of 8.4% sodium bicarbonate per 10 mL of local anaesthetic.¹¹

Topical local anaesthetics

Topical local anaesthetics are available in a variety of formulations and presentations. Their advantages include avoidance of first-pass metabolism, and avoidance of the risks of more invasive local anaesthetic techniques.

The 'ideal' topical local anaesthetic formulation will maximize permeability and absorption via the stratum corneum, while limiting systemic absorption hence toxicity.

Disadvantages of topical local anaesthesia include unpredictable absorption, uneven distribution or spread of the agent during application, and a failure of the occlusive dressings to stick to the skin. These agents should not be applied to broken, irritated or infected skin.

Topical anaesthesia lends itself well to procedures such as skin biopsy and removal, electrocautery and superficial laser therapy. It also enables painless needle insertion.

Cutaneous agents

The most commonly used topical agents are summarized in Table 4.4.

Mucosal agents

Examples of suitable ointments include cocaine 4%, benzocaine 5–20% and lidocaine 2–5%. Lidocaine is also available as an aerosol preparation.

Transdermal local anaesthetic delivery

In order for a drug to passively diffuse across the stratum corneum, it must be lipophilic, non-ionized and have a low molecular weight (<500 Da). Various technologies are evolving in further accelerating transdermal drug delivery.¹⁶

Table 4.2 Summary of local anaesthetics most commonly used in clinical practice

Class	Amides				Esters			
	Lidocaine	Mepivacaine	Prilocaine	Bupivacaine	Levobupivacaine	Ropivacaine	Procaine	Amethocaine
Local anaesthetic								
Onset of action	Fast	Fast	Fast	Medium	Medium	Medium	Slow	Slow
Relative potency	2	2	2	8	8	8	1	8
Duration of action (h)	Medium	Medium	Medium	Long	Long	Long	Short	Long
Maximum dose (mg/kg) ^a	3	5	6	2	2.5	3	7	1.0
Maximum dose with adrenaline (where applicable) (mg/kg)	7	7	9	2.5	3	4	10	1.5
Additional notes	Relative lack of vasodilatation Risk of methaemoglobinaemia				S-enantiomer of bupivacaine; modestly less cardiotoxic and neurotoxic	Pure S-enantiomer Lower propensity for motor block compared to bupivacaine Marked vasoconstriction at low concentration	Local vasodilatory action Lower propensity for motor block compared to bupivacaine Marked vasoconstriction at low concentration	Blocks reuptake of noradrenaline, thus can provoke hypertensive crisis and arrhythmias Potent vasoconstrictor

^aQuoted maximum 'recommended 'safe doses' vary. Most available data is extrapolated from animal studies. Other factors, including the site and speed of injection, are of greater relevance (see text).

Iontophoresis

Iontophoresis involves the application of a constant low-voltage direct current to actively transport drugs across a biological membrane.¹⁶ As ions move between positive and negative electrodes, they are actively transported through the skin. Drug molecules that are hydrophilic and ionized, thus ordinarily being skin-impermeable, are ideal for delivery by iontophoresis.

In the United States, the first Food and Drug Administration (FDA)-approved iontophoretically delivered local anaesthetic patch was LidoSite® (lidocaine hydrochloride 10% and adrenaline 0.1%). Pretreatment with sonophoresis may work synergistically to enhance drug delivery.¹⁶

Microporation technology

Microporation produces transient microchannels in the skin in order to form a conduit through which drugs may pass.¹⁶ Examples include the Painless Laser Epidermal System® (Pantec

Biosolutions AG, Liechtenstein). High-velocity, high-pressure 'needleless jet' sprays can deliver local anaesthetic in a similar way.

Sonophoresis

Sonophoresis employs the use of low-frequency (20–100 kHz) ultrasound waves to cause acoustic cavitation within the stratum corneum, resulting in the non-linear formation of acoustic microjets. The addition of surfactant material to the skin works synergistically to enhance the flux of hydrophilic molecules with large molecular weights that would ordinarily not traverse the skin membrane.¹⁶ Ultrasound can have a thermal heating effect, and induce convective transport, both of which may contribute to enhancing lipid permeability.¹⁶

Magnetophoresis

The application of a magnetic field causes an increase of the oil: water partition coefficient of drugs, making them move across biological membranes such as the skin by 'magnetokinesis'.¹⁶ Patch systems that employ this technology are currently in development.

Electroporation

Electroporation employs high-voltage (>100 V) pulses for microsecond bursts, causing formation of aqueous channels within the stratum corneum, providing a conduit for the diffusion of molecules. The time between the high-voltage pulses

Table 4.3 Equivalent drug concentrations for standard drug solutions

Drug solution	Drug concentration (µg/mL)
1 : 10 000	100
1 : 100 000	10
1 : 200 000	5
1 : 400 000	2.5

Table 4.4 Commonly used topical local anaesthetic preparations

Local anaesthetic	Trade name (pharmaceutical company)	Formulation	Application time (minimum–maximum)	Maximum dose/area	Particulars
Lidocaine 2.5% w/w + prilocaine 2.5% w/w	EMLA 5% (Astra Zeneca)	Cream + occlusive dressing	1–5 h	Adults: 60 g + 600 cm ² Children: 6–11 years: 20 g + 200 cm ² for 1–5 h 1–5 years: 10 g + 100 cm ² for 1–5 h 2–11 months: 2 g + 20 cm ² for 1 h <2 months: 1 g + 10 cm ² for 1 h	Not for use if <37 weeks gestation Not for use in infants (<12 months) taking methaemoglobin-inducing agents
Tetracaine 4% w/w	Ametop (Smith & Nephew)	Gel + occlusive dressing	30–45 min	Adult + child >5 years: max 5 tubes (1 tube = 1 g) at separate sites at single time Child <5 years: max 1 tube at single time	Not recommended for infants <1 month
Lidocaine 7% + tetracaine 7%	Pliaglis (Galderma)	Cream	30–60 min	1 mm layer (1.3 g of cream per 10 cm ²)	Not recommended if age <18 years Apply with spatula only Peel off skin prior to procedure
Lidocaine 4% w/w	LMX 4 (Ferndale)	Liposomal + occlusive dressing	30 min–5 h Child: 3–12 months: 4 h. <3 months: 1 h	Adult + child >1 year: 2.5 g Child <1 year: 1 g	

allows the skin to depolarize, thus avoiding interference with current flow.¹⁶

Future drug delivery

An evolving area of research in local anaesthetic delivery is that encapsulation matrices, where the properties of carrier molecules are used to enhance drug delivery and action.¹⁶

Liposomes are lipid vesicles that act as a drug reservoir for local anaesthetic. A lipid-soluble molecule is carried in the outer lipid bilayer, and aliphatic or hydrophilic molecules are contained in an aqueous interior. Liposomes are biodegradable, and can be administered by various routes (intravenous, topical, intramuscular, subcutaneous, nasal and oral). However, consistency in their manufacture is challenging, posing the risk of drug leakage of toxic metabolites.¹⁶

Other areas in development include microemulsions, hyaluronic acid-containing hydrogels, microspheres and nanospheres, injectable liquid polymers and bioadhesive films.

Local anaesthetic systemic toxicity

Local anaesthetic systemic toxicity (LAST) is a spectrum of neurological and cardiovascular signs and symptoms that result from the direct effect of local anaesthetics on neuronal activity within the central nervous system (CNS), autonomic ganglia and myocardium. The manifestation of these symptoms is related to the plasma concentration of the local anaesthetic, which is in turn dependent on:

- the dose of local anaesthetic administered,
- the rate of local anaesthetic absorption, distribution, metabolism and excretion, and
- the vascularity of the injection site.

Toxicity can present in a variety of ways, hence a high index of suspicion is paramount.

Symptoms and signs

Raised plasma concentration of local anaesthetics characteristically causes initial excitatory phenomena, secondary to suppression of inhibitory neuronal circuits. This is followed by nervous system and cardiovascular depression.¹⁷

CNS effects

The patient may complain of circumoral tingling, a metallic taste in the mouth, diplopia, dizziness and tinnitus. They may appear confused, anxious or agitated, or show signs of muscle excitability and twitching. Convulsions may occur.^{17,18}

CNS depressant effects manifest as apnoea and a reduced level of consciousness or coma.

Cardiovascular effects

Cardiovascular effects of LAST may initially stimulate sympathetic activity, resulting in hypertension and tachycardia. As plasma concentrations rise, this can rapidly evolve into ven-

tricular arrhythmias: ventricular tachycardia, including polymorphic ventricular tachycardia (torsades de pointes) and ventricular fibrillation.¹⁷ Consequently, refractory hypotension, heart conduction blocks or complete loss of cardiac output may occur.¹⁷

Toxicity varies between local anaesthetics, with more potent agents such as bupivacaine being more cardiotoxic compared to, for example, lidocaine. The clinical relevance of this is that cardiotoxicity with more potent agents is less likely to produce premonitory CNS signs, implying a narrower safety margin.¹⁷ Moreover, once malignant arrhythmias occur, they typically require prolonged resuscitation.

All local anaesthetics are arrhythmogenic and, with the exception of cocaine, have direct myocardial depressant effects.

Prevention of LAST

Facilities, including Local Anaesthetic Toxicity Toolkit, together with local departmental algorithms for treatment of LAST must be available in every theatre and recovery complex. All practitioners must be familiar with the location and usage of this apparatus.

Risk factors for LAST

Variables that may affect the risk of LAST include:¹⁷

- site of injection and vascularity,
- low cardiac output state,
- liver disease,
- pregnancy,
- acidaemia,
- concomitant use of sedatives, as these may mask symptoms or decrease the seizure threshold.¹⁹

Reducing the risk of LAST

The following practices reduce the risk of LAST:

- The use of the minimum dose of local anaesthetic required and adherence to maximum safe dosages.¹⁷ Note that the concept of 'maximum safe dose' is based mainly on extrapolations from animal data. It is clinically irrelevant unless the site, speed and route of injection are taken into consideration.
- Regular aspiration prior to injection (every 4–5 mL), ensuring slow, incremental injection.¹⁷
- Aspiration tests repeated each time the needle is moved. A negative aspiration test does not exclude intravascular injection, particularly if the needle is placed in a small vessel or a catheter technique is used.
- Use of pharmacological markers (e.g. adrenaline) to aid detection of inadvertent intravascular injection.¹⁷ Injection of a 2–3 mL local anaesthetic solution containing adrenaline 1 : 200 000 would be expected to induce a sympathetic response within 1–2 min should the needle be placed intravascularly.
- Regular communication with the patient, observing for symptoms of LAST.

- Routine monitoring of the patient during the recovery phase, in case of a delayed presentation of LAST.
- Use of real-time ultrasound-guided peripheral nerve blockade.
- Use of more dilute local anaesthetic solutions.
- Reduced doses of local anaesthetic in high-risk patients.

Management of LAST

Management of LAST is underpinned by three principles:

- restoration of the circulation to maintain tissue oxygenation,
- control of seizure activity, thus reducing oxygen consumption, and
- mitigating the systemic effects of local anaesthetics, particularly with respect with the cardiovascular system.

Management requires the expertise of the acute resuscitation team, usually led by an anaesthetist or intensive care physician.

All resuscitation team members, including surgeons, must be familiar with the resuscitation algorithm:²⁰

- 1 Stop injection of local anaesthetic and call for help. If in doubt, call the cardiac arrest team.
- 2 Start resuscitation (as per national protocols):
 - (a) Airway: maintain patency using chin lift/jaw thrust and airway adjuncts; intubate the trachea once skilled persons available.
 - (b) Breathing: ventilate both lungs with 100% oxygen; hyperventilating the patient (respiratory rate >20) may help to alleviate ensuing metabolic acidosis.
 - (c) Circulation: establish intravenous access. Control seizures by bolus administration of an intravenous benzodiazepines, barbiturates and propofol.
- 3 Start treatment:
 - (a) Start intravenous 20% lipid emulsion therapy:
 - Give 1.5 mL/kg bolus over 1 min and simultaneously start infusion at rate of 15 mL/kg/h.
 - Repeat bolus dose up to two times, with 5-min intervals between each bolus, should cardiovascular stability not be restored. In this instance, the background infusion rate should also be doubled to 30 mL/kg/h (after 5 min of starting the infusion).
 - The maximum cumulative dose of 20% lipid emulsion should not exceed 12 mL/kg.
 - (b) Treat arrhythmias as per nationally endorsed resuscitation guidelines. *Arrhythmias in LAST are typically refractory to treatment. Resuscitation may be prolonged.*^{17,20}
 - (c) Consider cardiopulmonary bypass in cases refractory to treatment.
- 4 Post-resuscitation management:
 - (a) Patients must be managed in a high dependency unit.
 - (b) Where 20% lipid emulsion has been administered, there remains a theoretical risk of acute pancreatitis for up to 48 h. Thus regular clinical assessment and serum lipase assays must be considered.

The standard practice of administering 1 mg of adrenaline, as advocated by most Advanced Life Support Algorithms, may exacerbate the arrhythmogenic state induced by LAST. For this

reason, general consensus is that adrenaline should be given at a reduced dose of <1 µg/kg.¹⁷

Methaemoglobinaemia

Methaemoglobin is formed when the the iron contained within haemoglobin is present in the ferric (Fe³⁺) rather than the reduced ferrous (Fe²⁺) state. The result is an inability to carry oxygen.²¹

Local anaesthetics implicated in the development of methaemoglobinaemia are, namely, prilocaine (which is metabolized to *o*-toluidine, which oxidizes haemoglobin to methaemoglobin), benzocaine and lidocaine.²¹

Methaemoglobin levels exceeding 1% are deemed abnormal. Symptoms manifest with methaemoglobin levels in excess of 10%, and include a slate-grey discoloration of the skin, fatigue, shortness of breath and generalized weakness, progressing to cardiac dysrhythmias and coma. Risk factors include pre-existing congenital methaemoglobinaemia, the administration of drugs with a high oxidative stress (e.g. phenytoin, sulphonamides) and age under six months.^{1,21} The latter is due to reduced level of NADH reductase enzymes.¹

Management of methaemoglobinaemia is with high concentration oxygen and the administration of a reducing agent such a methylene blue (1 mg/kg intravenously).

Regional techniques of relevance to plastic surgery

There are many regional techniques that lend themselves well to plastic and reconstructive surgery. The advantage of successful regional techniques compared to local infiltration is a more predictable area of anaesthesia, with minimal risk of tissue distortion.

The majority of regional techniques are carried out by anaesthetists. The use of ultrasound-guided blocks has become increasingly popular.

The following criteria must be fulfilled prior to the commencement of any regional anaesthetic technique:

- 1 Patient consent.
- 2 Exclusion of contraindications to block:
 - Absolute contraindications: patient refusal, local anaesthetic allergy (rare)
 - Relative contraindications: localized infection; coagulopathy
- 3 Confirmation, both verbal and written, of the site and side to be blocked
- 4 Patient monitoring
- 5 Resuscitation equipment and drugs
- 6 Presence of a trained assistant
- 7 An alternative management plan should the regional technique fail.

Intravenous regional anaesthesia (Bier block)

Indications

Surgery on the wrist or hand lasting less than 1 h (e.g. foreign body removal, release of tendon contractures).

Principle

Local anaesthetic is injected into the forearm previously exsanguinated by use of a tourniquet. Local anaesthetic diffuses from the venous circulation into surrounding nerve endings, providing anaesthesia below the level of the tourniquet. Prior venous exsanguination prevents dilution of the local anaesthetic, thus maintaining a sufficient concentration gradient for diffusion to occur.

The duration of the block is limited by tourniquet pain, which typically occurs after 30–45 min. Patients invariably require conscious sedation.

Technique

- 1 An intravenous cannula is inserted into the opposite arm ('systemic circulation' access).
- 2 A 22-gauge intravenous (IV) cannula is also inserted into the hand of the limb to be blocked ('regional circulation' access).
- 3 With the patient supine, the arm to be blocked is passively exsanguinated by elevation for 2 min.
- 4 A double-cuffed tourniquet is placed proximal to the limb that is to be blocked. Adequate padding between the skin and the tourniquet is essential to prevent skin necrosis. It is imperative that both tourniquet cuffs are checked for leaks.
- 5 An Esmarch bandage is applied to enhance limb exsanguination. At this point the distal cuff is inflated, followed by the proximal cuff. Once the proximal cuff is fully inflated, the distal cuff can be deflated. The cuffs are inflated to approximately 100 mmHg above systolic blood pressure.
- 6 The Esmarch is removed, and the distal limb is checked for pallor and the absence of a distal pulse. Local anaesthetic is then injected into the IV cannula of the exsanguinated limb.
- 7 For the upper limb, 12–15 mL of 2% lidocaine or 30–40 mL of 0.5% lidocaine is a suitable regimen. Onset of anaesthesia typically takes 5–10 min.

Complications

- *Tourniquet pain* typically occurs after 30 min. It is alleviated by inflating the proximal cuff and deflating the distal cuff, which may afford a further 30 min of operating time.
- *Local anaesthetic toxicity* can be avoided by ensuring correct function and application of the tourniquet, with clear labelling of the 'distal' and 'proximal' cuffs. At the end of surgery, the tourniquet should be released in a graduated manner, preventing a sudden washout of local anaesthetic into the systemic circulation.
- *Haematoma* the smallest possible gauge IV line should be used. Should there be failed attempts at IV cannulation,

pressure should be applied until bleeding stops, prior to limb exsanguination.

- *Engorgement of the extremity* occurs where arterial blood enters the limb in spite of the tourniquet, and venous blood is unable to escape. It can be avoided by ensuring good tourniquet function with a pressure of at least 100 mmHg above systolic.

Nerve blocks for the face

General considerations

- All three anatomical landmarks discussed below can be identified by imagining a line drawn vertically parallel to the midline of the face, intersecting a centred pupil.
- The eyes must be protected from cleaning solutions.
- The needle should never be inserted directly into the relevant foramina, as this may cause damage to the neurovascular bundle. If immediate paraesthesia is encountered on slow injection, the needle should be withdrawn and redirected.
- Topical anaesthesia should be considered for intraoral blocks.
- Commonly used agents include 1% lidocaine or 1% mepivacaine.
- A 23- or 25-gauge 25 mm intradermal needle attached to a 3 mL or 5 mL Luer syringe can be used.

Table 4.5 summarizes the relevant sensory innervation of important branches of the trigeminal nerve. For a more detailed description of trigeminal nerve anatomy, please refer to an anatomy textbook.

Surpraorbital nerve block

The supraorbital and the supratrochlear nerves can be blocked by a single injection technique.

Anatomy

The supraorbital nerve exits the supraorbital notch. At this junction, the nerve and its branches approximate with the orbital periosteum, underneath the obicularis and frontalis muscles. After giving off palpebral filaments to the upper eyelid, the nerve divides into medial and lateral branches, which fan out in a cephalad direction.

Landmark

Supraorbital notch (in a smaller percentage closed to form a foramen), palpated at the junction of the lateral two thirds and medial one of third of the inferior border of the supraorbital ridge; 2–3 cm lateral to the midline of the forehead.

Technique

The needle is inserted 1 cm medial to 0.5 cm immediately superior to the supraorbital notch. The needle is then withdrawn a few millimetres and redirected medially towards the junction of the orbital rim with the nasal bone; 2–3 mL is injected.

Table 4.5 Summary of sensory innervation of important branches of trigeminal nerve

Trigeminal nerve division	Nerve	Branch	Sensory supply (ipsilateral side)
Ophthalmic (V1)	Frontal	Supraorbital nerve	Upper eyelid Forehead Scalp (until lambdoid suture)
		Supraorbital nerve	Conjunctiva Lower medial forehead Skin of upper eyelid Frontal sinus mucosa
Maxillary (V2)	Infraorbital		Lower eyelid Side of nose Upper lip Facial gingiva maxillary premolars and anterior teeth
Mandibular (V3)	Inferior alveolar	Mental nerve	Anterior chin Lower lip to mentolabial fold Lower teeth

Supratrochlear nerve block

Anatomy

The supratrochlear nerve exits the orbit 1 cm medial to the supraorbital nerve. It passes above the trochlea of the superior oblique muscle, and courses cephalad, giving off several small terminal branches.

Landmark

The supraorbital notch (see above), as the supratrochlear notch is difficult to palpate, or else absent in some people.

Technique

The needle is withdrawn a few millimetres and redirected (along the line of the supraorbital ridge) approximately 1 cm medially towards to the junction of the orbital rim with the nasal bone; 1–2 mL of local anaesthetic is injected into the subcutaneous tissue in a fan-like distribution.

Application of mild pressure to the upper eyelid via a finger or roll of gauze while administering the aforementioned blocks may help to prevent palpebral oedema and/or ecchymosis (Figure 4.2).

(a)

(b)

(c)

Figure 4.2 (a) Supraorbital foramen (red dot); approximate positions of needle insertion for supraorbital (blue arrow) and supratrochlear (yellow arrow) nerve blocks. (b) Intraoral approach for infraorbital nerve block. (c) Intraoral approach for mental nerve block.

Infraorbital nerve block

Anatomy

The infraorbital nerve is the third branch of the maxillary (V2) division, which divides off within the pterygopalatine space, passing through the infraorbital fissure, along the floor of the orbit to enter the infraorbital canal. On exiting the canal, it gives off three terminal branches: the nasal, palpebral and labial nerves.

Landmark

The infraorbital foramen, located along the inferior border of infraorbital rim.

Technique

The cheek is retracted and the infraorbital foramen is continually palpated. The needle is inserted into the mucosa directed approximately 0.5 cm above the upper second bicuspid tooth, aiming cephalad and laterally towards the lower border of the foramen; 2–3 mL of local anaesthetic is injected.

Mental nerve block

Anatomy

The mental nerve is one of two terminal branches of the inferior alveolar nerve. It exits the mental foramen, an anterior opening of the mandibular canal. As it passes underneath the depressor anguli oris muscle, it divides into three further branches.

Landmark

The mental foramen, which is normally located between the two lower premolars in the adult, approximately 1 cm below the gum-line. In children, the foramen is at the junction of the first and second primary molars. There is some variability with the position of the foramen, however.

Technique (intraoral approach)

The cheek is retracted. The needle is inserted 0.5 cm above the mental foramen, and directed caudally; 2–3 mL of local anaesthetic is injected.

Where the foramen is not palpable, the nerve can be targeted by injecting the buccal mucosa at the junction of the two lower premolar teeth.

CHAPTER 5

Lasers

Se-Hwang Liew

Department of Plastic Surgery, Alder Hey Children's Hospital, Liverpool, UK

Introduction

Albert Einstein first proposed the concept of stimulated emission in 1927 and the first laser (light amplification by the stimulated emission of radiation) was developed in 1959 (ruby). Lasers were first used on human skin in 1963.¹

The use of these early lasers was crude, and damage to cutaneous tissues, and hence scarring, was common. It was not until the introduction of the concept of selective thermolysis by Parrish and Anderson in the 1980s² that the use of cutaneous medical lasers became commonplace. This concept has led to the development of lasers that can act on specific targets or 'chromophores' in certain layers of the skin, allowing for targeted therapy with minimal collateral damage in the form of scarring.

Laser physics

Laser light is produced by the release of a series of coherent, unidirectional photons of light. These photons are generated by an external light source or electromagnetic field, which is used to excite a specific medium. Different media, which can be in solid, gaseous or liquid state, are selected to produce different lasers.

The atoms in the medium *absorb* the energy from the external source, thereby exciting some of their electrons into higher energy levels. Upon relaxation back into resting state, the energy lost is released as a photon of light in a process known as *spontaneous emission*. These photons are incoherent and go on to excite other electrons into higher energy levels, resulting in multiple photons being spontaneously emitted throughout the material. This process continues until the number of electrons in the higher energy levels outnumbers those in the lower energy levels, resulting in a situation called *population inversion*. When this occurs, the high-energy electrons will cause the photons to drop down into resting orbit, emitting a further photon of the same frequency and direction which is *in phase* with the

incident photon without absorbing the incident photon. This process is called *stimulated emission* of photons and each photon released contains a specific amount of energy that is consistent throughout the material.

By placing the medium between two mirrors this process can amplify itself by allowing light that is produced at right angles to the mirrors to pass back and forth through the medium, producing increasing numbers of unidirectional, coherent photons which are then released, by transiently removing one mirror, as a laser beam.

Laser light has specific therapeutic properties that are exploited in medical use:

- **Monochromatic** – Lasers have a specific wavelength and so have the ability to selectively target chromophores.
- **Coherent** – Alignment of light waves allows high intensity to be focused over small area.
- **Compressible** – The high temporal coherence of waves allows for ultra short pulses that deliver localized energy.
- **Collimated** – Transmission of parallel rays of light without divergence allows for high localized intensity.

Principles of laser therapy in cutaneous treatment

Selective photothermolysis predicts that selective thermal damage of a chromophore will result when sufficient fluence (energy delivered per unit area – J/m²), at a wavelength preferentially absorbed by that target is delivered during a time (pulse duration) equal to or less than the thermal relaxation time of target.²

The use of laser in cutaneous treatment involves the selection of a specific wavelength that is preferentially absorbed by a specific target or chromophore in the skin. This specific target can be oxyhaemoglobin (vascular lesions), melanin (pigmented lesions) or water (skin resurfacing). Since the surrounding epidermis is spared, the treatment is specific with little injury to normal skin. The laser effect is influenced by a number of laser

parameters, including spot size, divergence/convergence of laser beam, wavelength, pulse duration and fluence.

The first two factors (spot size and divergence/convergence) are believed to be optimized in all modern lasers. The *spot size* of a laser affects the optical penetration of light if its radius is equal to or less than the distance for which light is free to diffuse within the tissues. Larger spot diameter will allow greater laser penetration due to greater internal reflection. Furthermore, a larger surface area can be treated faster. Most lasers therefore use a spot size that is greater than the penetrative depth of the laser (>4 mm).

The efficacy of laser treatment also depends on the *convergence* of incident light and the uniformity of irradiance. Convergence of laser light allows for less external reflection from the skin surface and therefore deeper penetration and more selective target injury.

Different chromophores in the skin are targeted by lasers with different *wavelengths*. Wavelength also affects the depth of penetration, with laser light with a longer wavelength penetrating deeper into the dermis.

The most selective target heating is achieved when energy is deposited at a rate faster than the rate of cooling of the target chromophore. Longer *pulse duration* will achieve more efficient heating but if the pulse duration is too long, there will be insufficient time for heat to dissipate, causing an undesirable temperature rise that will lead to damage to surrounding epidermis and dermis. These injuries could result in scarring or other cutaneous side effects. The time taken for heat to dissipate from a particular chromophore (the thermal relaxation time) in seconds is approximately equal to the square of the target's diameter in millimeters.³ In treating vascular malformations, where a variety of abnormal vessel diameters are present at different depths under the epidermis, the setting of an ideal pulse duration for treatment becomes difficult.

In addition to pulse duration, sufficient *fluence* is also required to achieve a damaging temperature in a target chromophore (therapeutic threshold). The use of higher fluence will increase the risk of developing skin complications during treatment.

Laser modality

A laser can be classified as operating in either continuous or pulsed mode. A *continuous* wave laser simply means that the laser emits a constant source of light without interruption, whereas a *pulsed* wave laser emits laser light at a predetermined duration and repetition rate. In a *Q-switched* laser, pulses are only emitted at peak intensity and for extremely short durations.

Most medical lasers are used in pulsed mode, as the targeting of chromophores becomes more specific with less thermal damage to the surrounding tissues due to the short thermal relaxation time of chromophores allowing heat dissipation

between pulses. A pulsed laser is used when the destruction of the target chromophore relies on heat denaturation or coagulation.

In a Q-switched laser, short pulses of high peak power laser light are emitted. Hence, it is used in conditions where a shattering effect is needed to destroy the target chromophores (i.e. pigmented lesions and tattoos).

Laser safety

Lasers can be broadly classified into four classes (Table 5.1). Most medical lasers used are class 4 and hence suitable precautions need to be taken while undertaking laser procedures.

The MHRA (Medicines and Healthcare Products Regulatory Agency) has produced a guideline on the safe use of lasers.⁴ All personnel who are associated with the purchase, supply, installation, use and maintenance of medical lasers and intense pulsed light (IPL) systems should be familiar with the document.

In addition, any hospital that undertakes laser treatment should have local safety rules, with a trained laser safety officer. The local safety rules should be specific to each clinical application and for each laser, and all personnel involved in laser use should be familiar with it. It involves the recommendation that all staff are appropriately trained for the use and maintenance of lasers, safety precautions and adverse events reporting.

Specific safety precautions

- *Eye protection* – Suitable eye protection should be used for each specific laser.
- *Smoke/plume extraction* – Smoke plume may contain hair particles, viable cells, bacteria, viruses, prions and other hazardous materials. Numerous toxic and carcinogenic gases will also be given off. It is therefore essential that precautions are taken to reduce such risks. A well-fitting, high-filtration-efficiency face mask (e.g. particulate respirators that filter particles of 0.1 µm in size) should be used. A standard surgical face mask is not sufficient to act as the primary method of particle filtration. This should be supplemented by a dedicated smoke evacuator. A standard medical vacuum system (e.g. an operating theatre wall suction system) is not suitable for smoke plume removal.

Table 5.1 Classification of lasers

Class 1	Lasers that are not capable of emitting hazardous levels of radiation under normal conditions
Class 2	Lasers that have visible wavelength lasers with lower power output, which will not cause permanent damage to the eye in the 0.25 s it takes to blink
Class 3	Lasers which, if viewed directly, can cause permanent damage to the eye
Class 4	Lasers that produce a hazardous emission, either through direct or scattered radiation. Suitable eye protection must be worn. There is also a potential fire risk

- **Fire hazard** – Flammable substances such as alcoholic skin prep should not be used in areas where lasers are used. Fire extinguishing equipment should be readily available. Care should also be taken when performing laser treatments near nasopharyngeal or endotracheal tubes.

Types of laser

The main types of lasers are divided according to the chromophores they target – oxyhaemoglobin (vascular lesions), melanin (pigmented lesions and hair removal lasers) or water (resurfacing lasers). *Ablative lasers* are resurfacing lasers, such as CO₂ and erbium:YAG lasers, which remove the epidermis. *Non-ablative lasers* selectively target the chromophores within the epidermis or the dermis only. Most lasers that are used to treat vascular, pigmented lesions or hair, and the IPL systems fall into this group. Commonly used lasers along with their wavelengths and target chromophores are listed in Table 5.2.

Fractionated lasers

With the advance of laser technology, fractionated lasers have been developed in the last decade to improve the safety profiles of the traditional ablative lasers. First used in 2004,⁵ fractionated lasers deliver laser beams that produce tiny columns of thermal injury called microthermal treatment zones (MTZs), interspersed with normal epidermis and dermis. As a result, healing is faster than the traditional ablative lasers, with less potential side effects. Both ablative and non-ablative fractionated lasers are available. The advantage of this system is that it allows the resurfacing of non-facial areas and also it allows deep penetration of the laser beam into the dermis, thus encouraging collagen remodelling.

Ablative fractionated lasers can either be based on erbium:YAG for superficial treatments or CO₂ for deeper treatments.

Intense pulsed light

Intense pulsed light (IPL) systems work on the same principle as the non-ablative laser systems. The main difference is that the system delivers a range of wavelengths between 500 and 1200 nm in each pulse of light (non-laser) rather than just one wavelength.

IPL systems work well for vascular and pigmented lesions and also improve mild rhytids. The proposed mechanism of action is thought to be thermal denaturation of dermal collagen, leading to inflammatory changes and subsequent collagen synthesis and remodelling.

When an IPL system is used to treat vascular lesions, no postoperative purpura is seen due to the longer wavelength resulting in more even heating of vessels. Its wide range of pulse width also allows treatment of large and small vessels.

Cutaneous side effects of laser treatment

Temporary

Cutaneous blistering and serous crusting are common after laser treatment. These normally resolve within a few days with no long-term sequelae. Patients are advised to keep the treated area clean.

Skin hyper- and hypopigmentation can occur and is more common in patients with darker skin types. The melanin in the skin competes with other chromophores in absorbing the laser energy, resulting in postinflammatory changes. If it occurs, it normally resolves with time, with or without application of topical skin depigmentation treatment.

Long term

Scarring can occur in severe cases of burn due to laser treatment. There is so far no indication that repeated laser treatment will result in any carcinogenic harmful effects to the skin. To reduce the incidence of cutaneous side effects, it is common for most modern lasers to have an incorporated cooling device. This can either be cold air, cryogen spray or contact cooling device.

In addition, clinicians have to ensure that patients' skin colour is at its lightest when treatment is undertaken. This reduces the melanin load of the skin which can compete with skin chromophores in absorbing laser energy. This can be accomplished by ensuring that patients undergoing treatments are not tanned during treatment, or by temporarily depigmenting the skin before laser treatment with topical products such as hydroquinone.

Table 5.2 Commonly used medical lasers

Medium	Laser	Wavelength	Chromophore
Solid	Alexandrite	755 nm	Melanin
	Nd:YAG	1064 nm (deep lesions)	Tattoo pigment
	KTP	532 nm (epidermal lesions)	Melanin
	Copper vapour	578 nm	Tattoo pigment
	Erbium:YAG	2940 nm	Oxyhaemoglobin
Liquid	Pigmented lesion dye	510 nm	Water
Gas	Carbon dioxide (CO ₂)	10 600 nm	Melanin
			Water

Laser treatment by lesion type

Vascular lesions

Vascular lesions that are responsive to laser treatment include port wine stain, haemangiomas, facial telangiectasia, rosacea, spider naevus, cherry angioma, erythematous scars and warts.

The gold standard *pulsed dyed laser* has a wavelength of 585 nm, and causes vaporization of blood, local rupture of microvessels and purpura. The efficacy of treatment of vascular lesions depends on vessel size, depth and wall thickness. Clinically, dark red or purple lesions tend to be larger and deeper and respond less favourably than the more superficial,

lighter coloured lesions. In treating port wine stain, a poorer response has been observed in lesions found on the extremities. The reason for this is unknown but it may be due to the effect of gravity or deoxygenation on the vasculature or possibly the increased vessel wall thickness of more distal vessels.

After treatment, purpura develops immediately and resolves in 1–2 weeks. Other side effects include scaling (12%), crusting (4%) and scarring (<1%).

Technical tips

- If a smaller spot size is used then higher fluence is needed to achieve similar clinical results.
- The multipass technique has been shown to achieve better results.
- Tissue cooling is important to reduce the incidence of epidermal injury caused by stacking pulses (treating the same spot by firing two pulses sequentially).
- Avoid using 755 nm and 1064 nm lasers around the eyes without metal guards protecting the globe. As they have deeper penetration they can injure the eyes by targeting the retina and iris and blindness has been reported.
- Larger spot size allows deeper tissue penetration.

Other types of laser helpful in treating vascular lesions

- *KTP* (potassium titanyl phosphate; frequency-doubled Nd:YAG laser) – Longer pulse width avoids rupturing target vessels, and hence avoiding purpura.
- *V beam* – Variable pulse width, and can be used to treat telangiectasia without as much purpura by using longer pulse width.
- *Alexandrite laser (755 nm)* – Targets oxyhaemoglobin, and hence effective for bluish/nodular/hypertrophic port wine stains.
- *Long pulsed Nd:YAG* – Longer wavelength, with deeper penetration, and hence more effective in deeper vessels (i.e. veins).
- *Sequential lasers* (e.g. Cynergy) – The first laser (pulsed dye) converts haemoglobin to methaemoglobin, which is then targeted by the Nd:YAG laser. This allows the use of a lower fluence of Nd:YAG.
- *Fractionated lasers* – Can be used to treat resistant port wine stains which has very little chromophore left as well as nodular port wine stains.

Pigmented lesions

Q-switched lasers are most commonly used to treat pigmented lesions. They target melanosomes, causing rapid heating, expansion and rupture. Q-switched frequency-doubled Nd:YAG (532 nm) and the pigmented lesion dye (510 nm) lasers are most useful for superficial epidermal lesions such as freckles (ephelides) and solar lentigines, whereas ruby (695 nm) and alexandrite (755 nm) lasers are of benefit in deeper lesions such as café-au-lait spots and naevi of Ota and Ito.

When using lasers to treat pigmented lesions, patients are always warned that sun exposure can cause the lesions to recur.

This is because the melanocytes that produce the pigmentation are not destroyed by laser treatment. Posttreatment hypopigmentation and hyperpigmentation can occur.

Care should be taken when treating melasma and postinflammatory hyperpigmentation. These conditions generally get worse after treatment.

Tattoos

Q-switched lasers are used to treat tattoos. The laser energy is absorbed by pigment particles, leading to fragmentation of the particles, which are then ingested by phagocytes and transported to the regional lymph nodes.

Black and blue ink absorb all wavelengths well and hence can be treated by a number of different lasers. Different coloured inks absorb different coloured wavelengths so different lasers are indicated to treat different colours: KTP for red, alexandrite for green, and 510 nm pigmented dye for red, orange, purple or yellow.

In general, 8–15 treatments are needed. Patients should be counselled that it may not be possible to completely clear the tattoos. This will result in a ‘ghost tattoo’ where only part of the tattoo is visible. Some patients may find this more unsightly than the actual tattoo itself.

The operator should be aware that in some circumstances ink darkening (reduction of ferrous to ferric oxide or titanium oxide) can occur. This is especially important if the tattoo is of ‘flesh’ colour. Allergic reactions from laser-induced release of tattoo antigens (e.g. chromium-containing red or yellow inks) have also been reported.

Sunblock should be removed prior to treatment as it may contain metal-containing oxides and salts (e.g. titanium dioxide) that may be flammable after exposure to high-energy laser pulses.

To improve results, recently Q-switched lasers with shorter pulse duration (picoseconds) have been used with encouraging results. Such short pulses in high fluence have been reported to be successful in generating a tremendous amount of pigment shattering.^{6,7}

Aesthetic applications

There are three main factors that contribute to an ageing face:

- gravitational effects that give rise to jowls and eyebrow ptosis, which are best dealt with by surgery,
 - reduction in volume, which can be corrected by injection of synthetic fillers or autologous fat; and
 - photodamage, a collective term to describe the effect of sun damage to skin, resulting in damage to collagen and elastin.
- Photodamage leads to the formation of fine wrinkles (rhytids) and poor skin texture and the formation of brown spots due to pigmentary dyschromia, and facial red spots or thread veins due to damage to superficial blood vessels. Facial fine lines can be improved by removing the top layer of skin by chemical peel,

dermabrasion or laser resurfacing. Laser resurfacing is better as it gives precise depth of ablation and controlled thermal damage with the added benefit of skin tightening. In laser resurfacing CO₂ and erbium lasers are used. Energy is absorbed by intracellular water, causing rapid heating and vaporization of tissue.

Most published series have reported an overall 90% improvement in rhytids following laser resurfacing. Most improvement can be expected in the perioral area and least in areas of dynamic wrinkling such as the glabella. The results decrease with time, probably due to delayed resolution of postoperative oedema (down to 31% in glabella in 2 years in one study).

In acne scarring, the maximum improvement that can be expected after one treatment is 30–50%. If resurfacing is used to treat pigmentary changes or lesions, there is a chance of recurrence.

CO₂ lasers

The CO₂ laser has a wavelength of 10 600 nm and is highly absorbed by water. It was first introduced in 1964, in continuous mode for cutting and coagulating tissues. The development of a high-energy pulsed mode in the 1990s expanded its use and made it the gold standard in skin resurfacing.

A conventional CO₂ laser deposits energy in the upper 20 µm of skin (after one pass) due to strong water absorption. There can be 0.2–1 mm of residual thermal damage, leading to prolonged downtime with long periods of wound healing. Re-epithelialization usually takes about 7 days with prolonged erythema that can last more than six weeks. Such thermal damage also leads to a high incidence of scarring and skin pigmentation changes. The thermal damage has an additional benefit of causing skin tightening.

In the mid 1990s, to reduce thermal damage and its associated side effects, modification was made to the CO₂ lasers so that only pulses that are shorter than the thermal relaxation time (1 ms) were used. This was achieved by either the use of high-energy, short-pulsed (<1 ms) CO₂ lasers (Ultrapulse), or a focused beam with rapid scanning resulting in contact time of <1 ms (Silktouch/Feathertouch/Sharplan).

Erbium:YAG lasers

The erbium laser was first used in 1996. It has a wavelength of 2940 nm and hence has 16 times higher water absorption compared to the CO₂ lasers. It penetrates 1 µm of skin (versus 20 µm for CO₂) and offers more precise skin ablation. It causes less thermal damage than the CO₂ lasers, and hence has a lower incidence of skin complications such as prolonged erythema and skin pigmentary changes. Due to the less significant thermal effect it offers poorer haemostasis and less skin tightening when used as a resurfacing tool.

Fractionated CO₂ lasers

To minimize the thermal side effects of the CO₂ lasers, fractionated CO₂ lasers were recently developed. They deliver evenly spaced thermal injury, surrounded by healthy skin, which

enables rapid epithelialization. Depending on the fluence used, re-epithelialization usually occurs between 3 and 6 days, and the side effects associated with thermal injury, such as prolonged erythema and skin pigmentary changes, are less common than with non-fractionated lasers. In addition, because intact skin is interspersed with ablated skin, the depth of ablation can be increased without the fear of scarring. This is useful in upregulating skin collagen production, which is most useful in skin tightening⁸ and improving atrophic scars.⁹

Histological examination of fractionated CO₂ laser-treated skin shows columns of thermally damaged skin with immediate inflammatory response, followed by reorganization of dermal matrix and collagen induction.¹⁰

Fractionated CO₂ lasers also allow resurfacing of areas outside the face, which is not possible with traditional resurfacing lasers. It also allows treatment of darker skin types without a high risk of skin complications.

There is some evidence that fractionated CO₂ lasers improve skin hypopigmentation and hyperpigmentation, as seen in conditions such as melasma. This is achieved by facilitating migration of melanocytes from neighbouring skin, and changing the optical characteristic of skin by increasing production of collagen.¹¹

The effects of fractionated CO₂ laser resurfacing depend on the depth of laser penetration, dermal coagulation and spacing. Normally 2–4 treatments are needed, at intervals of 6–12 weeks.

Preoperative consultation

It is important to elicit the patient's expectation from treatment, as well as their acceptance of treatment downtime and side effects before starting treatment. In preoperative history taking, the patient's skin type and scarring history must be noted. Roaccutane should be avoided for 9–12 months prior to treatment as it may compromise skin healing. If the patient has a history of cold sores, antiviral therapy should be started prior to laser resurfacing (aciclovir 400 mg three times daily from 24 h prior to treatment, and continued for 5 days afterwards). Treatment should ideally be offered when the patient has not had any recent significant sun exposure. Treatment of tanned skin may result in unfavourable pigmentation.

Patients should be warned of possible complications, including acne flares, prolonged oedema, erythema, postinflammatory skin hyperpigmentation and skin hypopigmentation.

Postoperative care

I favour the open technique, where no dressing is used to the treated area. The patient is encouraged to wash the area as normal in the shower, and keep the area clean. Skin oedema usually peaks at 48 h, and resolves over 6–8 weeks. Elevation and application of ice will help. Some patients experience pruritus, usually in the first 5 days. A cold compress or emollients will help. Erythema usually resolves gradually over 2–5 months, but may last for more than 3 months in 12–31% of patients. Patients should be encouraged to use total sunblock during this period of time.

Complications

- Infection (1–2%) – highest risk days 2–10. *Pseudomonas* (41%), *Staphylococcus aureus* (35%), *Staph. epidermidis* (35%), *Candida* (24%).
- Pain and itching.
- Follicular occlusion leading to acne or milia (up to 84%).
- Hyperpigmentation (30–40%), usually occurs 2–6 weeks post op, only lasting more than three months in 18% of cases. The incidence is increased with darker coloured skin (86–100% skin type IV and V). Sunblock/depigmenting agents can be used.
- Hypopigmentation (8–19%) – may not be evident until seven months post op. This reflects the degree of pretreatment photodamage and bronzing, as well as aggressiveness of resurfacing.
- True hypopigmentation – due to decreased melanogenesis.
- Pseudohypopigmentation – relative lightening of skin compared with surrounding untreated sun-damaged skin.
- Scarring (2–3%).

Laser hair removal

Laser hair removal is now the standard in long-term hair control.¹² Hair removal lasers with a wavelength of approximately 700 µm direct laser light precisely to each melanin-containing hair follicle. Several lasers are effective: the ruby laser (694 nm), alexandrite laser (755 nm), Nd:YAG laser (1064 nm) and the IPL source (590–1200 nm). Although the mechanism of follicular injury is likely to be thermal, the precise contributions of photo-mechanical damage or thermal denaturation to follicular injury are unknown. It is possible that after absorption of radiant energy, the large temperature difference between the melanosomes and their surroundings produces a localized rapid volume expansion, leading to microvaporization or ‘shock waves’, which cause structural damage to the hair.

Studies on the efficacy of laser hair removal show that long hair-free periods are achievable with all of the above lasers. Several treatments are needed, usually at 4–6 weekly intervals when the hair has regrown. The hair-free period is variable after a course of 6–8 treatments, but usually ranges from 3 to 6 months. Permanent hair removal is rare. Complications from treatment are usually uncommon, especially if a test patch is performed prior to full treatment, and is more common in darker coloured skin. The most common complication is redness after treatment, which lasts a few hours. Less commonly patients can expect crusting of skin, and skin hypo and hyperpigmentation. Most of these complications are temporary, with skin pigmentation changes usually recovering in 6–9 months.

The use of the Nd:YAG laser is more beneficial in patients with darker coloured skin. The absorption of laser light by melanin is low at 1064 nm, and hence will cause less heating to the epidermal melanin. The low melanin absorption is

somewhat counteracted by the deeper penetration of the laser light at longer wavelength, and the use of longer pulsed duration ensures the longer period of heating of the melanin in the hair follicles.

Other indications for laser therapy

- *Resistant warts* – Flat warts can be treated with the pulsed dye laser. Thick warts can be treated with ablative lasers. In the case of recurrence, topical treatment or pulsed dye laser can be considered.
- *Keloid scars* – Erbium laser ablation, followed by regular Adcortryl injection.
- *Scar resurfacing* – Fractionated CO₂ laser as per aesthetic resurfacing.
- *Cutaneous malignancies and premalignancies* – Premalignant conditions such as actinic keratosis and Bowen’s disease respond well to laser ablation, especially with the erbium laser. Erbium laser is also useful in treating superficial basal cell carcinoma, especially in patients with Gorlin syndrome, where repeated surgery can be disfiguring. The CO₂ or erbium lasers are useful in treating superficial in-transit melanoma.
- *Kaposi’s sarcoma* – Pulsed dye laser, photodynamic therapy, Nd:YAG and CO₂ lasers have been used with varying success to treat Kaposi’s sarcoma.

³Department of Plastic Surgery, Great Ormond Street Hospital, London, UK

Background

The process of tissue expansion in reconstructive surgery was first reported by Charles Neumann, who described its application for auricular soft tissue reconstruction in 1957.¹ Neumann simply applied concepts found in both normal physiological as well as pathological processes of the human body. Examples of this phenomenon include pregnancy, where the abdomen increases in size to accommodate the enlarging fetus, and rapid neoplastic growth, which may result in soft tissue expansion, deformity and eventual skin breakdown. African tribes have also adopted tissue expansion as part of their cultural background, enlarging facial structures such as the lip or the ear.^{1,2}

Nearly half a century later, tissue expansion was repopularized by Radovan for use in postmastectomy breast reconstruction,³ although its applicability soon became evident in other branches of plastic surgery. Tissue expansion enables soft tissue coverage of large defects secondary to burns, trauma, congenital malformations and cancer excision. It involves the insertion of an implant adjacent to a wound or defect that needs to be resurfaced. The implant is then incrementally enlarged by injection of isotonic saline, resulting in stretching of the overlying soft tissue. The expanded skin can then be used to resurface a defect or incorporate permanent prostheses, including those used for postmastectomy breast reconstructions. Tissue expansion exploits the principles of controlled mechanical skin overstretch in order to generate new tissues with ideal compliance and almost perfect skin colour, texture match and sensibility to the resurfaced defect.⁴

However, this useful tool on the reconstructive ladder does not come without its complications. In this chapter, we review the effects of tissue expansion on soft tissues and explore the tenets that govern its safe and effective use in the patient.

Viscoelastic properties of skin

The structural components of skin can be altered by expansion as demonstrated by several biomechanical studies. Its viscoelasticity means that the mechanical response to loading involves both a viscous (time-dependent) and an elastic (time-independent) component.^{5–7} Skin is mainly composed of dermis and epidermis. The predominant proteins in the dermal layer are collagen types I and III, which are produced by fibroblasts. In the relaxed state, their triple helical structure results in a wavy and convoluted alignment. Upon stretching, the collagen fibres straighten and realign parallel to each other.⁴ The skin's elasticity, essential for joint movements, is due mainly to superficial thin bundles of microfibrils associated with progressively larger amounts of amorphous elastin to form elastic fibres.^{8,9} Once strain is released, elastin fibres return collagen to its relaxed coiled posture.¹⁰ If stretched excessively, elastin is prone to fragmentation, resulting in a loss of recoil.¹¹ Viscoelastic properties change with age and repeated mechanical forces, resulting in skin laxity.⁵

Skin is a dynamic organ and acclimatizes to constant mechanical forces applied to it due to its viscoelastic properties (Table 6.1). On a tissular and cellular level, constant mechanical stress induces changes termed mechanical creep and biological creep. These phenomena interact to restore resting tension of stretched tissues to baseline – stress relaxation (Figure 6.1).¹² For example, a wound which was under tension intraoperatively but relaxed at outpatient follow-up is an example of stress relaxation.⁴

Creep is defined as the stretching of skin under a constant load over time. In order to explain the biomechanics of skin during the process of tissue expansion, a distinction was made between mechanical and biological creep.¹³ Mechanical creep

*These authors contributed equally to this chapter.

Table 6.1 Summary of the viscoelastic properties of skin

Mechanical creep	The elongation of skin under a constant load over time Collagen fibres stretch out and become parallel Elastin undergoes microfragmentation Interstitial fluid is displaced (e.g. during intraoperative tissue expansion and skin suturing under tension)
Biological creep	The generation of new tissue secondary to a persistent chronic stretching force (e.g. seen during pregnancy)
Stress relaxation	The tendency for this resistance of skin to a stretching force to decrease when held at a given tension over time

Figure 6.1 Principle of tissue expansion. Source: De Filippo *et al.*, 2002.¹² Adapted with permission of Lippincott Williams & Wilkins.

describes the clinically observed elongation of skin beyond the original stretch when placed under sudden constant tension and is thought to be attributable to the morphological changes (stretching) of the dermal framework in response to stress. Upon stretching, the formerly convoluted collagen fibres straighten and realign parallel to each other, resulting in the extrusion of fluid from the collagen network and microfragmentation of elastic fibres, thus making the skin more viscous.¹³

Biological creep occurs with the formation of new tissues as a result of a persistent chronic stretching force in an attempt to relieve the stress (stress relaxation). It underlies the mechanism of gap junctional disruptions, which results in cellular proliferation. Several studies have confirmed that the gain in skin surface area after expansion was caused by new skin formation rather than simply stretching the pre-existing skin. Over a period of 6–12 weeks, a multitude of growth factors, cytokines, adhesion molecules and signal transduction proteins are induced to stimulate epidermal thickening, with concurrent dermal thinning

Figure 6.2 Effects of tissue expansion on surrounding tissues. Stretching of surrounding tissues induces growth factors, which mediate cell proliferation and increased angiogenesis. Factors such as TGF- β influence extracellular matrix production while membrane-bound protein kinases, focal adhesion points and the cytoskeleton influence intracellular signalling cascades. Source: Takei *et al.*, 1998.¹⁴ Reproduced with permission of Lippincott Williams & Wilkins.

and collagen fibril alignment of the newly expanded tissues (Figures 6.2 and 6.3).¹⁴ In fact, a study conducted by Vander Kolk *et al.* demonstrated a significant increase in collagen production in expanded skins compared to control skins.¹⁵ Additionally, growth factors including epidermal growth factor (EGF), transforming growth factor beta (TGF- β) and platelet-derived growth factor (PDGF) are upregulated to stimulate neoangiogenesis of the expanded tissues. Deformational forces acting on the cell membrane and disruption of integrins reduce cell-matrix adhesion and induce conformational changes of membrane proteins. Calcium channels open, leading to signal transduction and cytoskeletal microfilament contraction. The actin cytoskeleton then transmits mechanical forces intracellularly, resulting in increased gene expression and mitosis via interaction with protein kinases, second messengers and nuclear proteins.^{16–19} Cellular proliferation then results in tissue enlargement.

Enhanced vascularity is among the most noticeable advantages of expanded tissues, exhibiting both higher vessel numbers and larger calibres compared to non-expanded counterparts.^{20–23}

Pietramaggiore *et al.* demonstrated that cyclic mechanical forces applied to the skin of living rats stimulated cell proliferation and vascular remodelling.²⁴ Additionally, a recent study by Erba *et al.* supported the angiogenic role of vascular endothelial growth factor (VEGF) in cyclic dermal stretching.²⁵ Stretched skin presented with more densely packed vessels as well as a significantly increased thickening. However, the most important change during tissue expansion is tissue proliferation secondary

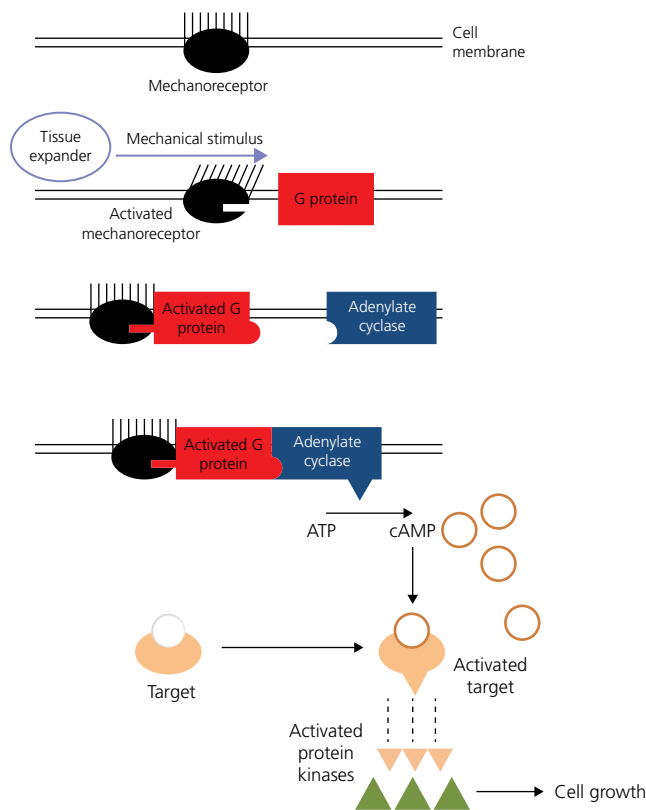

Figure 6.3 Molecular cascade in response to tissue expansion resulting in cellular proliferation. Source: De Filippo *et al.*, 2002.¹² Reproduced with permission of Lippincott Williams & Wilkins.

to stress-induced cellular changes (biological creep). Sheng *et al.* demonstrated that transplantation of angiogenic growth factor-secreting cells into expanding skins of rats resulted in accelerated tissue expansion, enhanced neovascularization of the expanded skin and promoted cell proliferation.²⁶ Expression of EGF, VEGF and basic fibroblastic growth factor (bFGF) were significantly enhanced in treated animals compared to control animals. Growth factor supplementation may well play an important role in the future of tissue expansion, both in reducing hospitalization times and flap retraction after expansion. Current research aims at evaluating the best possible source of growth factors. Wang *et al.* demonstrated increased tissue regeneration efficiency and reduced skin shrinkage when expanding tissues were exposed to bone marrow mesenchymal stem cells (BMMSCs).²⁷ The gene expression of important growth factors such as VEGF, bFGF, EGF and stromal cell-derived factor (SDF) was significantly enhanced in exposed tissues compared to sham treated tissues. Local administration as opposed to systemic infusion of BMMSCs even further enhanced growth factor expression, which is supportive of the substantial role these factors play in tissue regeneration following expansion. Because of their relative inaccessibility within the bone marrow and the invasive nature of BMMSC harvest, scientific research looks to alternative sources of growth factor-secreting stem

cells. Adipose-derived stem cells (ADSCs) are ubiquitously available and have several advantages over other sources. They are easily accessible in large quantities, can be obtained via a minimally invasive harvesting procedure and their isolation yields a high amount of stem cells. Several studies demonstrated that wound supplementation with ADSCs significantly accelerated regeneration.^{28–30}

Tissue changes during expansion

In order to fully understand the mechanics involved in tissue expansion, we will first familiarize ourselves with the structural components of skin. Skin is a multilayered structure and has three well-defined anatomical regions.^{31,32} The outermost layer, the epidermis, forms a thin, uninterrupted and protective layer across most of the body's surface but contributes little to the skin's mechanical properties.⁷ The bottom layer, the hypodermis, is mainly made of fatty tissues and serves as an insulating layer. The middle dermal layer holds most of the skin's adnexae, including nerve endings, sweat and oil glands and consists of three main structural components that underlie the skin's strength and elasticity: collagen, elastic fibres and extrafibrillar matrix. The dermis can be further divided into papillary and reticular layers. The papillary dermis contains thin collagen fibrils which are packed together into thicker collagen fibres (Figure 6.4). Only about 15% of the dermis is type III collagen, most of which is found in the papillary layer. Collagen type I, the most abundant building block in vertebrates, is the principal protein providing tensile strength to the skin.^{33,34}

Austad *et al.* assessed the effects of tissue expansion on the mitotic activity in the epidermis in order to address the question whether there is a net gain in epidermal tissue.¹³ Their studies confirmed that tissue expansion caused a marked increase in epidermal mitotic activity in a guinea-pig model. Studies on 17 human volunteers supported this finding as Pasyk *et al.* demonstrated a significantly thickened epidermis of expanded human skin compared to non-expanded skin.¹⁴ Although expanded tissues maintain their phenotypic characteristics, mechanical strain induces an increase in DNA synthesis and therefore cellular proliferation.^{7,15} Biochemical pathways involved in this process include cytoskeletal, extracellular enzyme, membrane and cytosolic components that converge together to convert the pathway of mechanotransduction seen in tissue expansion into a cellular response, ultimately leading to cellular proliferation.¹⁵

The dermis, in contrast, becomes thinner upon stretching, with hair follicles moving further apart. It may take up to 2 years for the thickness of this layer to return to normal. In keeping with animal models, Pasyk *et al.* assessed the effect of expansion on the dermis in 14 patients and identified significant thinning of the dermis.¹⁴ This, however, was not found to be rate-dependent. Furthermore, dermal thinning after expansion was noted to be equal in children and adults.

Figure 6.4 Schematic illustration of the composition of collagen in the dermal matrix.

Subcutaneous fat tissues were also found to thin after expansion. Adipocytes were flattened, surrounded by fibrosis, or disappeared altogether during the expansion process. Similarly, skeletal muscles are known to undergo atrophy after expansion resulting in the so-called 'bath-tub depression'. Histologically, the atrophic muscle cells are surrounded by fibrous tissue and demonstrate abnormally arranged sarcomeres, large amounts of sarcoplasm and also numerous large mitochondria.¹⁴ As opposed to the changes in muscle tissues, the loss of subcutaneous fat is permanent.

Enhanced angiogenesis in expanded tissues versus non-expanded counterparts is of clinical significance and presents an advantage in flaps raised on such skin. Improved survival of flaps raised on expanded skin shows properties similar to a delay phenomenon. This was confirmed by Cherry *et al.* who, using a pig model, elevated random pattern flaps in expanded tissues or non-expanded tissue to determine whether these flaps survived for the same time intervals.¹⁷ Flaps raised on expanded tissue had the greatest increase in surviving length, averaging 117% over control flaps, which was in large part due to an increased vascularity as well as vasodilatation in the angiograms of skins expanded over a period of five weeks.¹⁷ The pressure and mechanical stresses applied to expanding tissues resulted in tissue hypoxia, which induced the formation of an increased microcirculation in expanded tissues.¹⁸ Sasaki *et al.* also demonstrated that flaps based on expanded tissue survive to a greater length than non-expanded or delayed as undermined bipedicle flaps.¹⁹ Increased vascularity is thought to result from increased gene expression and significantly higher levels of angiogenic factors such as VEGF in expanded tissues compared to non-expanded controls.^{20–22}

Rapid rates of expansion have further been demonstrated to increase flap microvasculature compared to slowly expanded

tissues. However, it should be noted that rapidly expanded tissues may become profoundly hypoxic up to 48 h which may compromise flap survival.¹⁸ In addition, significant patient discomfort accompanying rapid tissue expansion may limit the rate of expansion.

Types of devices

Each tissue expander needs to be carefully selected for its desired purpose, making tissue expansion a highly individualized procedure. Depending on the size and shape of the defect to be covered, different expander types may be selected (Figure 6.5). The basic design is an inflatable silicone elastomer reservoir.² Isotonic saline is delivered in a controlled fashion via a valve port system which is either integrated into the expander or connected to the prosthesis via silicone tubing (Figure 6.6). An integrated system offers the advantage of undermining a single pocket for expander placement, but also places the implant at risk of perforation by a misplaced needle. Internally placed remote ports remove the danger of expander perforation, but introduce potential complications, including kinking of the port, tube obstruction and migration. To avoid these complications, the undermining for the port pocket is minimal, the port is placed over firm, supporting tissue and, if need be, the port position can be fixed with sutures.³⁵ Externally placed portals have proved particularly useful in the paediatric population as they may alleviate pain and anxiety associated with frequent injections²⁴ and the safety of such ports has been demonstrated repeatedly.²⁵

The shape of the expander is governed by the anatomical location and may, if necessary, be custom made to fit any size or

Figure 6.5 Variation in shape of tissue expanders: (a) spherical; (b) rectangular; (c) cylindrical; (d) crescent.

shape. Circular expanders are best suited to areas such as the breast, whereas crescentic and rectangular shapes have been described for the scalp and lower limbs, respectively.² A further parameter governing tissue expansion involves directional expansion in order to impart a certain contour to the expanded pocket.⁸ This may be of importance if a specific shape is required, such as for breast reconstructions.

In 1982, Radovan successfully applied a temporary tissue expander for postmastectomy breast reconstruction.³⁶ Such procedures, however, require a second surgical intervention to remove the expander and replace it with the final breast implant. Two years later, Becker described a permanent expander for breast reconstruction where a modified inflatable breast implant enables a reservoir to be attached and detached at a side-filling valve.³⁷ The implant therefore functioned both as a tissue expansion device and a permanent implant upon removal of the reservoir. In a more recent study, the Becker implant was compared prospectively to the two-stage expansion process in a randomized study and patient satisfaction was measured.³⁸ Seventy patients were randomized to receive either a round permanent Becker implant ($n = 35$) or undergo a two-stage reconstruction with a crescent-shaped expander ($n = 35$), later replaced by an anatomical implant. Thirty patients were excluded and therefore only 20 patients per group were evaluated. A

significant 70% of patients in the Becker implant group underwent revision surgery secondary to upper pole fullness and poor ptosis. It was therefore concluded that a two-stage procedure achieves a better aesthetic outcome.

In an effort to minimize these traditional disadvantages of conventional tissue expanders, a new generation of pressure-sensitive self-expanding devices was first described in 1982. Austad and Rose created a permeable silicone balloon filled with a hypertonic NaCl solution which drew in body fluids down the osmotic gradient.³⁹ Despite being described as having some value for soft tissue reconstruction, these osmotic expanders are rarely in use nowadays due to major disadvantages.⁴⁰ First, there were relatively long inflation periods of 8–14 weeks. Second, high incidences of balloon rupture during the early stages resulted in necrosis of the overlying tissues.⁴¹ More than a decade after its initial conception, Wiese developed an osmotically active expander that was completely independent of the use of saturated saline. The implants exploited the osmotic forces of hydrogels, which consist of two components: a polymer network with constant quantity and an aqueous component that is variable.⁴² The gel is placed subcutaneously and absorbs body fluids from the extracellular space. Water uptake then causes gradual swelling of the hydrogel. The theoretical advantages of self-inflating expanders, including less frequent hospital visits and

Figure 6.6 Schematic illustration of submuscularly placed tissue expanders. (a) An integrated injection port system allows saline injections directly into the expander whereas saline is injected into a distal port in (b).

injections as well as reduced anxiety and pain, led to their commercialization and distribution by Osmed (Ilmenau, Germany).

However, a recent case series using Osmed self-expanders conducted by Chummun *et al.* demonstrated high incidences of expander infection among the paediatric population (2 out of 7, 28.5%), device migration and in some cases tissue ischaemia and necrosis.⁴⁰ The fact that a small study population and single-centre study was selected should be taken into account before prematurely dismissing self-expanding implants, however.

Basic incision and design plan

Tissue expansion requires meticulous preoperative planning, careful placement of the expander and suitable incremental inflation. Without these sequential steps the final result would be compromised.^{43,44} Placement is dictated by where the proximity of the defect is situated and this must be determined in advance after careful consideration of all possibilities. Easily recruitable sites of high tissue laxity should be determined before selecting skin of similar colour, texture and hair-bearing quality to the recipient site.⁴⁴ Tissue expansion may take up to 3–6 months depending on the anatomical site and the size of the expander.² Breast and abdominal tissues can tolerate large expansion volumes in one sitting, while forehead and scalp

expand more slowly.² The characteristics common to ideal expander placement are: (a) easy accessibility through a small incision, (b) gradual enlargement over a relatively short time period, (c) no painful inflation spikes, (d) good long-term biocompatibility with the body, (e) resistance to infection and extrusion, and (f) no need for revision procedures.⁴⁵

Selection of the ideal type, size and shape of the expander requires some foresight in terms of the timetable for the inflation process, which must be individualized to the patient in question.¹⁵ Radovan advised that the expander base should have the same size as the defect to be reconstructed as this allows for doubling of the surface area, enabling eventual coverage of both the donor and recipient sites.³ In contrast, other investigators postulate the use of as large a tissue expander as possible, however without empirical evidence.^{43,46}

In an effort to prevent arbitrary expander selection, several mathematical models have been developed to precisely calculate necessary dimensions. Early computational programs required the implant base diameter and the desired surface area gain to estimate the capacity of a spherical tissue expander.⁴⁷ More sophisticated programs are able to calculate the volumes of rectangular tissue expanders after feeding the length and breadth of the lesion to be repaired, considering them the size of the base of the expander. Raposio *et al.* incorporated a 'correcting factor' by multiplying the surface requirements by 3/2 to account

Figure 6.7 Round (a) and rectangular (b) osmotic tissue expanders. The hydrogel (middle) is wrapped inside a loosely fitting silicone membrane (left) that contains pores for finely tuned water uptake.

for potential tissue loss during tissue transfer.⁴⁰ However, software-based predictions of tissue expander size and shape are complicated by factors such as the surface on which the expander is placed upon. If placed over rigid flat surfaces, predicting the outcome of tissue expansion is straightforward. The difficulty occurs when expanders are placed over soft tissues with the tendency for inward compression or in areas of concavity, since the prediction of tissue expansion is less reliable. Due to such complexity, mathematical models failed to cross over to clinical routine where the trained surgeon's eye remains the ultimate, still arbitrary, judge.^{37,38}

The primary incision is best placed perpendicular to the direction of expansion to avoid tension across the incision, which could result in wound dehiscence and broadening of the scar line.⁴⁸ The ideal type of initial incision is still a matter of debate. However, no debate surrounds the issue of the ideal size; regardless of the type of incision, it should be as small as possible. Incisions can be made either at the junction of normal tissue and scarred area (i.e. paralesional incision) or remotely, so healthy tissue approximates healthy tissue. Paralesional incisions offer the advantage of minimal undermining of tissues for the insertion of expanders and their rates of infection, wound dehiscence and implant exposure do not seem to be statistically different to those in remote incisions. The latter, however, may offer better healing. There is, as yet, no final consensus as to which type of incision is definitely superior. This calls for controlled, randomized studies on site-specific expansions.

Another important consideration is the plane into which the expander is placed, as minimizing stress on overlying skin flaps aids during procedures such as mastectomies and increases the flexibility in choosing the final breast volume⁴⁸ (Figure 6.7). Before placement of the expander into the pocket, meticulous haemostasis is warranted and a closed system suction drain is put in place. Irrigation with povidone-iodine and/or gentamycin/cefazolin is commonly performed to minimize the chance of infection, followed by intravenous administration of antibiotics effective against skin flora.^{43,49}

After expander placement, the expansion process is usually delayed to allow the wounds to heal and reduce the chances of wound dehiscence.⁵⁰ This also allows for any swellings to subside and problems with the skin flap to reveal themselves.⁴³ The expander is filled until the patient feels some discomfort or the overlying skin blanches, but excessive tension on the expander flap should be avoided as tissue necrosis may ensue. Finally it should be noted that despite meticulous planning and appropriate technique expansion may not be successful. Success is also dependent on patient comorbidities, nutritional habits and local tissue factors.² Finally, patient cooperation to the expansion procedure is vital, as the process requires several interventions and involves many visits to the outpatient clinic.

Advantages and disadvantages of tissue expansion

Tissue expansion has many notable advantages to other plastic and reconstructive techniques. The expanded tissue usually provides sufficient soft tissue coverage for both the recipient as well as donor sites. Tissues from locally expanded sites allow same colour, texture, sensation and quality skin to be used in resurfacing a defect, thus avoiding the use of split-thickness skin grafts which are associated with more recipient and donor site morbidities^{15,51} (Figure 6.8a,b,c). Additional advantages include the significantly higher vascularity of expanded tissues providing more robust skin coverage.

Disadvantages of tissue expansion include the long timeframe of up to several months for the expansion process to finish and multiple outpatient visits. Most commonly, a two-stage procedure is necessary – one to place the expander in and a second one to replace the temporary implant with a more permanent one. Significant complications may result in multiple interventions. Further disadvantages include the frequent outpatient visits for incremental tissue expansion which can be particularly uncomfortable on the forehead and distal extremities. There is also a

(a)

(b)

(c)

Figure 6.8 (a) Expansion process used to reconstruct a large defect secondary to vascular malformation. (b) Explanted expanders in same patient. (c) Final result after advancing expanded tissues and excision of vascular malformation. An optimal colour and skin quality match has been achieved.

psychological impact of tissue expansion as there is a temporary disfigurement that can last for many months before the expander is removed.² Finally, tissue expansion is not without risks, and many large case series have noted major complications such as infection or implant exposure. A summary of associated complications is given below.

Complications

Tissue expansion, like any surgical procedure, comes with its own set of complications. In 1984, Manders *et al.* summarized their experience with 41 expanders in 35 patients and divided the observed complications into major and minor categories.⁴⁶ Major complications include infection, implant extrusion and flap ischaemia and may interrupt the expansion process. Minor complications, including seroma formation, scar widening, dog ear formation, transient pain and neuropraxia, may resolve without failure of the procedure.

Antonyshyn *et al.* performed a critical review of their results on tissue expansion over a 5-year period.⁵⁰ Sixty-six expansions were performed on 66 patients. Complications were identified and analysed based on their anatomical location, time of onset and detrimental results on the final outcome. Interestingly, the authors of this study noted some common sequelae of tissue expansion which, strictly speaking, were not complications. Transient pain following implant inflation was a commonly observed side effect, which was particularly associated with expansions of the distal extremities, dorsal trunk and forehead. Clinically significant complications were most frequently observed with head, neck and lower extremity expansion (39% in their case series) but generally did not affect the final outcome and excellent results were noted in 83% of cases. More serious complications tended to occur at the final stages of expansion with implant failure, neuropraxia, bone resorption and late implant exposure being highlighted. Haematoma formation requiring prompt evacuation was observed in only one patient. Similarly, cellulitic infection of the skin covering

the reservoir dome was observed in one patient only and was successfully treated with intravenous antibiotics. More severe complications, including infections involving the implant cavity and implant exposure secondary to incisional dehiscence, erosion through inadequate soft tissue cover and pressure necrosis of soft tissues, were observed more frequently.

Pandya *et al.* assessed complication rates of expansion at non-limb versus limb sites in a retrospective case series of 88 patients.⁵² The overall incidence of complications was higher in the limb group (43%) compared to other sites (27%). Lower limb complications were also more frequently observed than upper limb complications (47% versus 30%). They noted that exposure or infection of an implant on the extremity was not necessarily a sign of preceding failure. In these circumstances, expansion was suspended, appropriate antibiotics were administered and the area of exposure was allowed to heal. If the latter steps were successful, tissue expansion was restarted. The anatomical and physiological differences in the extremities could explain the higher complication rates. First, the extremities are in frequent motion and the underlying musculature can exert disruptive forces to the expander. Second, the flaps designed on the extremities are more difficult to encompass a curvilinear biconvex surface necessary for successful tissue expansion.

Fischer *et al.* examined significant preoperative risk factors associated with failed tissue expander placement in breast reconstruction.⁵³ In their analysis they utilized the American College of Surgeons National Surgical quality improvement program data sets from 2005 to 2010 to determine perioperative risk factors associated with early expander loss. A multivariate regression analysis demonstrated several preoperative patient conditions that are associated with early device loss: age >55 years, obesity and active smoking. Deep wound infection was the strongest predictor of loss (odds ratio (OR) 9.1, $p < 0.001$).⁴⁸ Patients with burns injuries have also been found to have greater complication rates during tissue expansion.⁵⁴

Future of tissue expansion

Expansion of skin and subcutaneous tissues adjacent to the pathological skin to be replaced is probably the only method of reconstruction that creates almost normal structure, anatomy and function in reconstructive surgery. This, however, may lead to the technique being restricted to patients with normal tissues surrounding the pathological defect. Furthermore, complications, especially in certain anatomical areas, are frequent, leading to further restrictions in terms of patient eligibility. In the future, as the underlying cell biology and molecular basis of tissue expansion is elucidated, former restrictions and complications may be overcome. We are now witnessing a revolution in the field of regenerative medicine and tissue-engineered expanders will surely follow. For example, the expander's material could be used as a carrier to deliver signals that 'manipulate' cell proliferation, vascularity and function. This may shorten the expansion time and increase the available expanded tissues.

In summary, tissue expansion is an important reconstructive tool in the armamentarium of plastic surgeons. It can overcome tissue shortages in challenging scenarios, providing an excellent colour, quality, sensitivity and tissue match for the defect site. However, as discussed in this chapter it is not without its complications and patients undergoing this procedure should be appropriately consented about the timeframe and what to encounter during the process.

Ten golden rules of expanders

- 1 Select a donor site where the consistency of the soft tissues are identical to those required to close the defect.
- 2 The access incision for the tissue expander should be placed at the margin of the defect and ideally through unscarred and non-radiated tissues.
- 3 Rectangular expanders give the most tissue expansion. Rectangular expanders increase surface area by 38% in contrast to round, which only give 25%.
- 4 The amount of fluid injected into the expander should be individualized to the patient and governed by tenseness, blanching of the overlying skin and pain. Care in preventing overexpansion will reduce the chances of tissue ischaemia and necrosis of the skin flaps.
- 5 The tissue expander should be sited on a base that resists mechanical deformation and directs the force of expansion outwards and towards the overlying soft tissues (e.g. bone).
- 6 The pocket which is dissected for tissue expander placement must be larger than the dimensions of the expander.
- 7 Delay implant inflation for approximately two weeks until sufficient time has passed for the wound to heal and oedema to settle. This will reduce the chances of incisional dehiscence and will allow time for problems with the flap to reveal itself.
- 8 One must recall that the capsule around the expander is highly vascular and capsulectomy can compromise the vascularity of the overlying skin.
- 9 Complication rates vary in tissue expansion depending on anatomical location. Extremity lower limb expansion has been shown to have higher rates of major complications in comparison to the scalp and the breast.
- 10 An exposed expander can be salvaged and expansion resumed in some cases.

CHAPTER 7

Tissue engineering

Lara Yildirimer and Alexander Seifalian

Centre for Nanotechnology & Regenerative Medicine, UCL Division of Surgery & Interventional Science, University College London, London, UK

Nanotechnology meets tissue engineering

More than 30 years ago, scientists at the Massachusetts Institute of Technology (MIT) first began researching into 'living skin equivalents' and vascularized scaffolds, leading the way into the era of tissue engineering (TE).¹ The main driving force behind the progression of TE to date is the prevailing organ donor shortage but it was not until 1987 that the term 'tissue engineering' was defined at a National Science Foundation meeting as 'the application of the principles and methods of engineering and life sciences towards the fundamental understanding of structure–function relationships in normal and pathological mammalian tissues and the development of biologic substitutes that restore, maintain, or improve tissue function'.² The pivotal strategies underlying TE have been identified as the use of (a) isolated cells or cell substitutes, (b) tissue-inducing substances and (c) cells placed on or within matrices.¹ This rapidly emerging field combines the principles of bioengineering, cell transplantation and biomaterials engineering to create platforms that resemble as much as possible the body's own native tissues in order to stimulate tissue and organ regeneration for transplantation. The amalgamation of biological and artificial components in such a way as to achieve active repair, structural maintenance and targeted reconstruction is the ultimate goal of TE. Basic building blocks including cellular components such as stem cells and scaffolds which may act as inert structural supporting frameworks and/or delivery vehicles for biologically active molecules may be superimposed in various different ways to create suitably specific scaffolds (Figure 7.1).

Several experimental studies have used TE approaches to successfully regenerate skin,^{3,4} bone,^{5,6} cartilage,^{7,8} musculature^{9,10} and fatty tissues^{11,12} and applied to surgical problems, TE has a clear potential to make a substantial difference by facilitating surgical procedures, accelerating postoperative wound healing and developing new surgical strategies. Current TE techniques mostly rely on the use of porous scaffolds which act as supporting structures for initial cell attachment and subsequent tissue ingrowth.^{13–15} Although relatively successful at providing basic platforms for cell

adherence, their usually macroscopic internal architecture lacks submicroscopic environmental cues which are normally found within natural extracellular matrix (ECM) (Figure 7.2), thus limiting the cells' inert capabilities to stimulate regeneration of relatively large or complex tissues.¹⁶ In order to generate constructs capable of inducing and enhancing natural cellular behaviours, researchers sought to develop structures that no longer served only as cellular adhesion platforms, but could also operate as independent agents capable of interacting with their environment to actively stimulate and guide tissue regeneration.¹⁷

The emergence of nanotechnology and its integration into the medical arena carries the field above and beyond former limitations, thereby igniting a wave of interest for the exploration of research into biotechnological systems at the nanometre scale. With regards to TE, the emergence of nanotechnology ('nano-engineering') has revolutionized the approach to fabricating tissues and organs, since the manufacture of novel biosynthetic scaffolds with enhanced material properties enables scientists to develop controllable and application-specific biomaterials. Novel biomaterials of nanometre dimensions are particularly attractive as they can closely mimic the molecular structure of tissues and organs, thus providing an ideal environment for cellular interactions and tissue regeneration. Scaffolds with nanostructured surfaces capable of incorporating bioactive agents have thus been developed to enable finer control over cellular positioning, organization and interactions.¹⁸

This chapter focuses on the main determinants for successful engineering of tissues and whole organs. Particular attention will be paid to the importance of stem cells as well as physical parameters of scaffolds, including material dimensional surface characteristics (micro- versus nanoscale features) and mechanical properties that, when orchestrated correctly, can act in synergy to recuperate lost function and aesthetics. Further, the ability to exploit the fundamental principles of nanotechnology will be discussed within the realms of TE to create hybrid, biologically active organ replacements based on the synergistic interplay between composite and nanocomposite materials and cellular or bioactive components. A new generation of silica nanocomposite

scaffolds based on polyhedral oligomeric silsesquioxane (POSS) nanoparticle-integrated poly(carbonate urea)urethane (POSS-PCU) will be critically debated in the context of their materials properties and their immense clinical translational potential, exemplified via the world's first in-human transplantation of a fully synthetic tracheal replacement and several more applications.

Pluripotent stem cells in tissue engineering

With the recent discovery of adult somatic stem cell reprogramming, the enticing prospect of theoretically limitless self-renewal, pluripotency, as well as differentiating capacity of induced pluripotent stem (iPS) cells catapults the field of

TE above and beyond theoretical model systems, as any cell type may now theoretically be induced in virtually limitless amounts. The notion of creating genetically designed and patient-specific pluripotent stem cells for research or clinical application has already progressed to tentative reality in the cases of human iPS cells derived from amyotrophic lateral sclerosis (ALS) and inherited spinal muscular atrophy patients which were successfully differentiated into motor neurons, the cell type destroyed in these two conditions.^{19,20} Further diseases with realistic potential to benefit from iPS cell technology include Parkinson's disease, Huntington's disease and Down syndrome among several more.²¹ In particular, the area of regenerative medicine could be revolutionized with the use of iPS cells, as scientists, doctors and patients would no longer be reliant on donated organs but could populate three-dimensional scaffolding structures with the patient's iPS cells and differentiate those into the required cell lineage.

Although theoretically brilliant, several substantial hurdles must be overcome prior to successful implementation of pluripotent stem cell-derived tissues in the clinic:²²

- The genetic stability of pluripotent stem cell lines must be thoroughly assessed and maintained throughout long-term culture and differentiation conditions to eliminate the potential for transformation and teratoma formation.
- The differentiation potential of iPS cells must be fully elucidated and a robust method for consistent differentiation into the relevant and functional tissue types must be determined.
- The molecular and functional characteristics of cells derived from pluripotent stem cells must be elucidated.
- The immunological determinants and engraftment potential of allogeneic pluripotent stem cell-derived cells are yet to be ascertained.
- Ethical issues regarding pluripotent stem cells, particularly those derived from human embryonic stem (hES) cells must be resolved.
- Finally, the progenitor or differentiated cells must be able to self-assemble or 'sense' directional cues within a 3D tissue engineered construct with appropriate cell–cell and cell–matrix interactions.

Despite such barriers, recent efforts to combine promising pluripotent stem cell technologies and TE concepts have gained valuable insight into cardiovascular,^{23–26} bone,^{27,28} cartilage,²⁹ nerve³⁰ and liver³¹ regeneration.

To begin with, the different sources of human stem cells within the body will be presented before highlighting the important role of local environmental cues in directing these stem cells down the predetermined lineage. The prior notion that cells isolated from specific tissues may only renew and differentiate into lineages of its host tissue has now been challenged, suggestive of considerable plasticity and ability to cross-over lineage restriction boundaries to give rise to cells of other lineages.³²

Human embryonic stem cells – an ethical dilemma

In 1998, James Thomson first harvested hES cells from the inner cell mass of blastocyst-stage embryos (from day 5 post fertilization) and subsequently cultured these on a mouse embryonic fibroblast feeder layer.³³ It was found that highest yield derivation was achieved by harvest and culture of the entire inner cell mass of the blastocyst. Subsequent studies have demonstrated the feasibility of harvesting embryonic cells prior to the blastocyst stage, during the morula stage (day 3–4 post fertilization). Rates of successful derivations, however, remained lower compared to those of blastocyst-stage derived cells.^{34,35} Further predicting factors for poor hES cell yield include embryo storage conditions and quality prior to derivation attempts. Prematurely arrested or highly fragmented embryos rarely derived cell lines, whereas those which have achieved blastocyst stage represent a solid source of hES cells.³⁶

Due to ethical concerns regarding the use of hES cells, efforts at stem cell derivation without embryonic destruction have been made and several different cell lines have been obtained using single-cell biopsies from morula-stage embryos.³⁷ Despite ongoing efforts, currently available protocols remain labour-intensive and are thus unlikely to become widespread.

Blastocysts may also be generated from unfertilized oocytes via asexual fertilization – a process termed parthenogenesis, which relies on chemical or electrical stimuli to induce development. Parthenogenesis may prove particularly useful in regenerative therapies as HLA homozygous hES cell lines could be derived from HLA heterozygous donors, possibly rendering this technique suitable for generating and banking HLA-matched hES cell lines.^{38,39} It remains to be seen whether hES cell lines will serve as renewable cell sources in the future since prohibitively large ethical concerns bar in-depth research using embryo-derived components.

Human induced pluripotent stem cell sources

With the seminal discovery 'that mature cells can be reprogrammed to become pluripotent' a new era of stem cell research with theoretically unlimited potential has begun. The ability to extract adult somatic cells and induce these to express genes important for maintaining properties of hES cells has already proved a useful tool for drug development and *in vitro* disease modelling. In 2007, Thomson and Yamanaka independently demonstrated the feasibility of reprogramming embryonic and adult human fibroblasts using only four transcription factors each. Takahashi *et al.* retrovirally transduced the four genes *Oct4*, *Sox2*, *KLF4* and *c-Myc* to revert differentiated adult human dermal fibroblasts into a pluripotent state⁴⁰ based on previous studies of factors known to reprogram murine somatic cells to induced pluripotent stem (iPS) cells.^{41–44} Yu *et al.* used lentiviral transduction of *Oct4*, *Sox2*, *Nanog* and *Lin28* to reprogram human foreskin fibroblasts and achieve pluripotency.⁴⁵ It was demonstrated that these iPS cells expressed cell markers characteristic of hES cells, including Ssea-3, Ssea-4, Tra-1–60, Tra-1–81, alkaline phosphatase, Nanog, Oct3/4 and Sox2.

Additional similarities to hES cells such as high telomerase activity,⁴⁶ histone methylation patterns,⁴⁷ embryoid body formation,⁴⁸ directed differentiation to cells in each of the three germ layers⁴⁹ and teratoma formation in mice⁵⁰ were observed in iPS cells. Slight variations in overall gene expression patterns were deemed minor and in line with regular line-to-line variations observed between hES cell lines.⁵¹

Despite such fundamental progress in stem cell science, prohibitive barriers, including the use of the oncogene *c-Myc* and an integrating retrovirus for gene transfer, had to be eliminated prior to adoption of iPS cells into the field of TE and regenerative medicine. Retroviral integration of transcription factors pose concerns due to possible transgene reactivation events and insertional mutagenesis of genes at integration sites which can alter the cell's subsequent biological behaviour and result in tumorigenicity, as observed in some patients who underwent gene therapy for X-linked severe combined immunodeficiency (X-SCID).⁵² It is therefore deemed crucial to generate iPS cells using non-integration methods.⁵³ In 2008, Okita *et al.* successfully induced pluripotent stem cells using non-integrating plasmid transfection but observed substantially lower iPS cell generation efficiency compared to transduction with retroviruses.⁵⁴ It remains to be determined whether a lower transgene expression with plasmid transfection is the underlying reason for relatively lower efficiency in iPS cell generation. Simultaneously, Zhou *et al.* reprogrammed murine embryonic fibroblasts to a pluripotent state using direct protein transduction.⁵⁵ Valproic acid and recombinant Oct4, Sox2, KLF4 and *c-Myc* proteins were fused to polyarginine protein transduction domains to obtain reprogrammed cells. Although this method has not yet been demonstrated in human cells, a similar approach is likely to be effective.

Stem cell plasticity

Poor iPS cell generation may not only depend on degrees of transgene expression but seems to be fundamentally affected by the somatic cell source. It has been shown that reprogramming efficiency was higher with human keratinocytes compared to human fibroblasts, with fewer viral integrations in keratinocyte-derived iPS cells, supportive of a higher degree of reprogramming efficiency and less genomic damage.⁵⁶ Besides the somatic cell source, other factors affecting differentiation efficiency of iPS cells include donor age and the specific method used for reprogramming. As evidenced by numerous studies, human iPS cells may be obtained from a multitude of somatic cell sources. Studies using transgenic mice containing the four reprogramming transcription factors have demonstrated iPS cell harvest from different cell types, including neuronal progenitor cells, keratinocytes, hepatocytes, B cells and fibroblasts of murine tail tips, kidneys, muscles and adrenal glands.⁵⁷ Such diverse origins enable the engineering of a range of tissues or organs such as bone, cartilage, muscle, marrow stroma and tendon.^{58–60} However, once cells are isolated from their natural habitat, they also lose their natural cues, potentially resulting in changes in

their phenotype and differentiating abilities. Although some studies attempted direct transplantations of cell suspensions without a scaffold, it soon became apparent that a lack of control over the localization of transplanted cells required the use of a protective delivery vehicle.^{61,62} Several studies thereafter and more recently have demonstrated enhanced capacity of cell delivery, viability and engraftment using both synthetic and naturally derived biomaterial scaffolds.^{63,64} However, once seeded, stem cells continue to depend on external signals to differentiate down a desired pathway.

Numerous studies have investigated a plethora of growth factors which when delivered alongside stem cells 'persuade' those to switch on specific genes to enable controlled differentiation into mature tissue-specific cells.^{65–67} Despite being routinely used in basic and clinical research, the combination of growth factors and stem cells for TE purposes elicits a feeling of unease due to the theoretical potential of tumorigenesis;⁶⁸ the feature most sought after in stem cells – continuous self-renewal – simultaneously may give rise to tumours due to transformations of normal stem cells. Equally, similar signalling pathways may regulate self-renewal in stem cells and cancer cells. The boosting of said pathways by a cocktail of growth factors remains a prohibitive feature for the transition of many promising TE strategies into clinical reality. Therefore, in an effort to harness the undoubted potential of stem cells, science re-evaluated their focus and concentrated on the influence of physical factors such as scaffold surface topographies and mechanical properties on the differentiation potential of stem cells. Zhu *et al.* demonstrated controlled differentiation of mesenchymal stem cells into osteoblasts when cultured on grooved biological nanofibres (width of 6.6 nm) equipped with osteogenic peptides.⁶⁹ Similarly, Kumar *et al.* showed that bone marrow stem cells grown on nano-rough surfaces obtained by solvent etching induced osteogenic differentiation and proliferation, whereas unetched scaffolds did not.⁷⁰ Further, cellular morphology was significantly different when grown on rough compared to smooth surfaces, indicating a significant role in surface roughness not only in directing cellular differentiation but also in dictating morphology.

The next section will delve further into the physical properties of TE scaffolds and their influence on cell fate.

Physical characteristics of tissue engineering scaffolds direct cell fate

Stem cells, although equipped with extraordinary intrinsic potential, require an inductive external environment in order to fulfil their desired functions. Unlike most other cell types, stem cells may differentiate into several different lineages. However, like most other cell types they are governed, to a large extent, by a supportive ECM capable of providing just the right cues at just the right times. It is thus up to the scientist to attempt to recreate such a space by means of designing a suitable scaffold. This section will focus on the development of TE scaffolds and

their importance in terms of directing (stem) cell fate and differentiation. The myriad of different fabrication techniques will be critically appraised in the context of clinical translatability. A particular focus will be placed on the differences observed between micro- and nanotechnological approaches in scaffold synthesis and related to cellular compatibility and host tissue responses.

The aim to create biomimetic scaffolds (i.e. a dynamic physical surrounding which replicates the cell's natural environment as closely as possible) makes use of a diverse range of materials including naturally derived or synthetic materials. More and more, a shift to taking a combinatorial approach harnessing the advantages of biological and synthetic biomaterials while cancelling out their individual drawbacks is favoured. The following paragraphs will discuss the importance of the physical environment in terms of TE scaffold design, pros and cons of commonly used biomaterials and the feasibility to create an exact replica of the human ECM.

Micro- versus nanotechnologies in scaffold fabrication

Despite a relatively advanced knowledge of the necessary physical environment required for cell growth, engineering a structurally ideal scaffold remains challenging. Current TE strategies as well as clinically used regeneration templates mainly focus on macrostructured porous scaffolds which primarily aid in initial cell attachment as demonstrated both *in vitro* and *in vivo*.^{13,15,71,72} Although relatively successful at reconstructing or replacing simple structures, developments of more complex tissue and organs in terms of both physical size and functionality are currently limited.⁷³ This is mainly due to insufficient or delayed vascularization of scaffold constructs and subsequently inhibited oxygen and nutrient delivery and removal of waste products. A recent study by Bai *et al.* demonstrated the crucial importance of scaffold pore size and pore interconnectivity for the development of blood vessels.⁷⁴ Interestingly, their data suggested that a pore size of up to 400 µm and numerous pore interconnections resulted in the most vascularized scaffolds. The strong link between scaffold macroporosity and enhanced vascularization potential was further demonstrated by several other studies.^{75–78} However, other studies found that in the *in vivo* setting, pore size was of lesser relevance compared to, for example, the degrees of chemical crosslinks present in TE scaffolds.⁷⁹

Macroporous structures may be advantageous for blood vessel formation but have been demonstrated to be detrimental for the proliferative capacity of certain cell types. It is well known that different cells respond to different pore sizes such that bone cells, for example, prefer larger pore sizes whereas fibroblasts preferentially grow and proliferate on scaffolds with significantly smaller pore sizes.^{80–82} Such discrepancies are thought to be due to the individual ECM characteristics of specific tissue types and must be taken into account when designing TE scaffolds. A further challenge in the design of TE scaffolds is the optimization of

interactions occurring at the cell–material interface. As complex tissues and organs demonstrate highly defined and organized structures, the growing field of nanobiotechnology has enabled scientists to refine scaffold architectures to obtain a much finer control over cellular positioning, organization and cell–cell as well as cell–matrix interactions.¹⁸ Tailoring of precise features on the material's surfaces enables the development of nanotopographies which render such materials unique and capable of controlled interactions with their environment. In fact, today's goal of TE is to create not merely simple substrates for cellular adhesion, but 'smart' platforms that are actively involved in tissue development and regeneration.¹⁷ Figure 7.3 illustrates the range of different sizes and proportions found within the human body to highlight the importance of nano-sizes in terms of cell–matrix recognition.

Bottom-up versus top-down scaffold fabrication methods

The motivation to create TE scaffolds with nanotopographical features stems from the knowledge that natural tissues and ECM components are composed of nanostructured cues.^{83–85} Cells then respond to such cues, which influence the material's surface properties, including surface chemistry, charge, wettability, topography and surface energy.^{86–88} Nowadays, nanotechnological advances in materials science and biotechnology are more and more able to create spatially controlled surface-specific adjustments down to a micro- and nanoscale, which encourages anchorage-dependent cells to recognize 'foreign' surfaces as natural, resulting in biological interactions, cell growth and differentiation.⁸⁹ This ability of cells to direct their own position and orientation on the basis of surface topographies is called mechanosensing.⁹⁰ Converting these physical forces into intracellular biochemical responses is referred to as mechanotransduction.⁹¹ These interactions between biomaterials and cells are primarily influenced at the interface between these two entities and attempts at recreating such surfaces involves the use of micro- and nanotechnological fabrication methods.

Such fabrication methods can be subdivided into two areas according to two different concepts: bottom-up and top-down approaches (Figure 7.4). The former mainly involves material self-assemblies, whereas top-down TE approaches include methods such as photolithography, microcontact printing, microtransfer moulding, capillary force lithography, scanning probe lithography and electrospinning.⁹² Both approaches, although coming from opposing ends of the materials science spectrum, require the same intricate knowledge of materials surface properties and the potential to trigger a variety of molecular events and processes. In both cases, scientists must understand the principles of device miniaturization, kinetic processes and cell biology to excel. The aim of bottom-up scaffold fabrication is to create modular units which assemble into larger tissue constructs with predetermined micro- and nanoarchitectural features.⁹³ This may be achieved through self-assembled

Figure 7.3 (a) A schematic representation of biological entities on a scale ranging from pico-sized atoms to macroscopic organs. Not to scale. Inspired by (9). (b) Cells behave differently on microstructures compared to nanostructures.

Figure 7.4 A schematic representation of the bottom-up and top-down concept.

aggregation, microfabrication of cell-laden hydrogels, cell sheet synthesis and direct printing of cells.

The underlying theory is based on the concept of tissue fluidity and fusion of cell aggregates as observed in embryonic development during which tissues may be considered as liquids.⁹⁴ Bottom-up approaches are generally based on the use of bio-ink containing cells, a bio-printer or ink dispenser and a temporary support for the deposited ink.^{95,96} Through controlled deposition of cell-containing ink, bottom-up fabrication methods can carefully engineer complex structures such as vascular trees and multilayered structures containing multiple, but spatially distinct cell

types. This has proved useful as recently documented by Koch *et al.*, who bioengineered a 3D skin construct composed of multicellular collagen layers deposited using a laser bio-printing system.⁹⁷ Cell viability and proliferative capacity was found to be adequate over a period of 10 days, with different cell types remaining distinct throughout the study period.

In addition to cell printing, bottom-up fabrication methods allow for the incorporation of cell-signalling factors within slowly degrading bio-ink and a more precise recreation of the natural extracellular environment. Bottom-up self-assembly approaches are not rarely inspired by nature itself; nanostructures may be

obtained by biologically inspired self-assembly as demonstrated by amphiphilic peptide self-assembly into hydrogels for TE strategies.⁹⁸ Bottom-up approaches rely on the incorporated cells' own production of ECM to create a supportive and non-immunogenic structure. However, insufficient ECM production in some cell types is thought to limit cellular migration and formation of cell–cell as well as cell–matrix junctions.⁹⁹ Furthermore, the harsh, relatively non-permissive conditions created by injuries and the lack of nutrients is thought to result in poor cell engraftment.^{100–103}

Top-down fabrication methods involving the use of biodegradable scaffolds as a longer term substrate for cellular adhesion, proliferation and new tissue formation may thus be required. Cells and cell-signalling factors may further be incorporated into such scaffolds and subsequently released in a temporo-spatially controlled fashion, either within a dynamic bioreactor system or *in situ* to accelerate functional regeneration.^{96,104,105} Scaffolds may consist of natural or synthetic biomaterials, or of a combination of both material classes to create a composite scaffold. The ideal scaffold for TE purposes should actively guide tissue formation, recuperate lost function and deliver cells and/or cell-signalling factors by mimicking, as close as possible, the natural bioenvironment. Despite ongoing research into scaffold fabrication methods, the ideal system remains elusive which, to a large part, may be due to the ambiguity of beneficial and detrimental scaffold characteristics, thus requiring more focused research.

The future of material fabrication for TE purposes has been suggested to lie in a combinatorial approach to harness the structural support provided by top-down fabricated scaffolds and versatility implemented by nanodimensional features within bottom-up assemblies. Such complementary, 'intelligent' scaffolds would then be able to actively regulate the development of ingrowing cells by providing external cues with or without supplementation with trophic signalling factors.

The next section will critically appraise the current status in TE of artificial organs and tissues in the context of a novel nanocomposite material, POSS-PCU, which draws its benefits from nano-sized surface structures as well as mechanical properties ideally suited for TE scaffolds.

Tissue engineering of artificial organs

The field of TE has come a long way, but demands for replacement organs and tissues still far outnumber currently available treatment strategies, rendering millions of individuals dependent on altruistic organ donations. In such circumstances, glimpses of hope involving clinical applications of engineered artificial organs go a long way in boosting scientists', clinicians' and patients' spirits. In this section, we will present and discuss the first-in-human applications of several different POSS-PCU-based TE organs and obtain a further insight into other promising tissues which are thought to reach the clinical setting fairly soon. We will bring together the concepts of stem cells and

organ scaffolds to demonstrate the ultimate goal, which is to create whole functional organs. At the end, the current situation in TE and regenerative medicine will be critically appraised within the realms of feasibility, current limitations and suggestions of how we may overcome these.

First-in-human applications of tissue engineering organs

In our laboratories, we have developed and patented a family of novel polymeric nanocomposites, POSS-PCU, for the development of synthetic organ scaffolds and the regeneration of viable tissues. The fusion of nanotechnology with regenerative medicine for the development of TE organ replacements guides us one step closer into a future independent from organ donation schemes – a feat recognized to solve a multitude of fundamental clinical as well as ethical issues. The capacity for successful replacement and regeneration of critically non-viable organs and tissues using our POSS-PCU nanocomposite scaffolds has been demonstrated in several recent high-profile first-in-human cases and exemplified by the transplantation of the world's first completely synthetic TE trachea which clearly demonstrated proof-of-concept for this new nanocomposite material.¹⁰⁶

TE trachea using the novel nanocomposite POSS-PCU seeded with autologous stem cells

Tracheal cancer, although one of the rarer neoplasms, is characterized by a high mortality rate and is conventionally managed with surgical resection and primary reconstruction.¹⁰⁷ However, the insidious onset and subsequently delayed diagnosis results in most primary malignant tracheal cancers presenting as inoperable diseases with 5-year survival rates of 5%.¹⁰⁸ A further obstacle to recovery includes the sheer lack of reconstructive options, rendering complete tumour resection unsafe in more than 40% of cases.¹⁰⁹ Attempts at transplanting TE tracheal substitutes into human patients using a decellularized human donor trachea as a base scaffold reseeded with bone marrow-derived mesenchymal stem cells and respiratory cells have provided first insights into the anatomical, physiological and biomechanical properties required for optimal TE tracheal replacement.¹¹⁰ It was found that apart from the prevailing donor organ shortage, mechanical instability and unpredictable functionality and immunogenicity rendered decellularized tracheal scaffolds ultimately unsuitable. Consequently, an alternative, tailor-made synthetic tracheal scaffold was fabricated using the nanocomposite material POSS-PCU (Figure 7.5) and transplanted into the tracheobronchial airway of a patient with recurrent primary tracheal cancer.¹⁰⁶ *Ex vivo* seeding with autologous mononuclear cells¹¹¹ and growth factor supplementation resulted in early reepithelialization of the transplanted TE construct.

The results of this first-in-human bioengineered artificial tracheal transplantation provides proof-of-concept for TE organ and tissue systems. Further research will have to focus on evaluating cell differentiation and ultrastructural organization on the transplanted construct.

Prior seeding with autologous bone marrow-derived stem cells enabled rapid integration into the host system and epithelialization with bronchial cells. (b, c) Realistic replicas of a nose and ear of two different patients made from POSS-PCU.

Lacrimal duct engineering using POSS-PCU nanocomposite

Lacrimal drainage obstructions causing excessive tearing, blurry vision and infections are common problems, which are usually tackled either by perforation of the obstruction, dilatation of the narrowed portion or bypassing a total obstruction. Although lower lacrimal duct obstruction can be treated with almost perfect success rates, canalicular (upper or presaccal) obstructions can only be insufficiently addressed with currently available therapies. Due to the extremely small diameter of the canaliculus (<1 mm), restenosis and stent failure are frequently observed. Bypass tubes, although temporarily effective, frequently encounter mucous blockage necessitating manual cleaning or replacement. Tube dislocation represents an additional complication.¹¹²

The ideal lacrimal duct conduit should inhibit scar formation to prevent later obstruction or dislocation. It should further be of anatomically suitable size (internal diameter ~1 mm), yet kink resistant but elastic and compressible to allow surrounding muscles to pump tears forward into the nasal cavity.¹¹³ The novel POSS-PCU nanocomposite material with its highly viscoelastic, biocompatible and non-immunogenic properties further exhibits a relatively 'non-stick' surface, ideally suited as a lacrimal duct drainage material (Figure 7.6).¹¹⁴ Several patients have so far benefited from this new artificial canaliculus.

Artificial vascular bypass graft using POSS-PCU nanocomposite

Cardiovascular diseases are responsible for over 20% of global mortality and represent the primary cause of death worldwide.¹¹⁵ Once pharmacological interventions prove unsuccessful, transplantation of vascular grafts remain the only realistic option. Autologous blood vessels are the ideal candidate in terms of long-term outcome. However, only about a third of patients have viable, autologous tissues available for harvest.¹¹⁶ Currently used prosthetic grafts such as expanded polytetrafluoroethylene (ePTFE) or polyethylene terephthalate (Dacron)^{116,117} are relatively successful as larger diameter grafts but tend to collapse or occlude once their internal diameter drops below 6 mm due to their inherent thrombogenic material surface¹¹⁸ and their relatively non-compliant mechanical properties. Besides, the use of prosthetic grafts in the paediatric population gives rise to a whole plethora of further complications related to the child's somatic growth, which necessitates frequent reoperations¹¹⁹ resulting in considerable morbidity.¹²⁰ These disadvantages led to the development of TE vascular grafts that attempt to facilitate the regeneration of lost or damaged blood vessels while remaining patent and antithrombogenic even at relatively smaller diameters.

In 2001, Shin'oka initiated the search for the optimal TE vascular graft by fabricating a biodegradable TE vascular graft based on polycaprolactone/polylactic acid copolymer reinforced with woven polyglycolic acid and seeded with autologous cells obtained from one of the patient's peripheral veins.¹²¹ Subsequent attempts to clinically translate TE vascular grafts based on either synthetic, decellularized or autologous scaffolds achieved relative success.^{122–128} However, the engineered conduits used in all of the above instances had internal diameters of more than 6 mm. It appears that below this value, graft patency becomes critical, necessitating a different approach to TE small diameter vascular grafts. The nanocomposite material POSS-PCU has demonstrated excellent patency in even smaller diameter grafts (see section above on lacrimal duct conduit) and has recently been transplanted as an ilio-femoral bypass graft in a first-in-human procedure (Figure 7.7).

The ability of POSS-PCU grafts to resist thrombo-occlusion, calcification and degradation has previously been extensively studied and confirmed.^{129–131} Based on the hypotheses that

Figure 7.6 An artificial lacrimal duct conduit made of POSS-PCU. The internal diameter is <1 mm but kink-resistant and non-occlusive. In clinical use.

material hydrophobicity favours platelet and protein repulsion and yet amphiphilicity allows for endothelial cell attachment, it was postulated that the integration of the hydrophobic POSS nano-cage into a more hydrophilic PCU backbone will create a material with both anticoagulant as well as cyto-attractant properties. In addition to antithrombogenicity, several other factors have been found to contribute to long-term vascular graft patency; a viscoelastic profile similar to native arteries as well as the potential for luminal endothelialization is known to create favourable conditions preventing intimal hyperplasia and luminal thrombus formation, respectively, two factors intrinsically associated with early graft failure.

The graph in Figure 7.8 compares the viscoelastic profiles of native arteries with (a) conventionally used replacement conduits made of Dacron or PTFE, (b) veins and (c) vascular grafts made of POSS-PCU. POSS-PCU grafts exhibited an exceptionally suitable compliance profile very similar to that of native arteries, particularly in comparison to Dacron or PTFE grafts which did not demonstrate any significant degree of compliance. The inherent viscoelasticity of POSS-PCU vascular grafts stems from the alternating soft and hard segments of the PCU backbone with variations in respective percentages determining the degree of elasticity and hardness. This certainly affects long-term graft patency *in vivo*, where compliance mismatch between native artery and Dacron/PTFE grafts results in thrombus formation secondary to turbulent blood flow at the junction between native artery and graft as well as the development of intimal hyperplasia, eventually culminating in luminal narrowing and graft failure.

In several *ex vivo* and *in vivo* large animal studies, we have demonstrated the endothelialization potential of POSS-PCU vascular grafts and heart valves, a technique further enhanced

by modifications of the surface luminal aspect via peptide functionalities.^{132–134} Modifications of vascular graft interfacial surfaces are aimed at regulating (a) cell-surface interactions, (b) protein and platelet adsorption and (c) thrombin formation (and eventual blood coagulation) in order to optimize patency rates. In general, surface morphology and nanotopography directly influence a material's chemical characteristics and are, in turn, directly dependent on both intrinsic properties such as the material's molecular structure, composition and molecular weight¹³⁵ as well as extrinsic surface modifications including physical and chemical alterations and biofunctionalization.

Other tissues and organs based on POSS-PCU with substantial clinical potential

It is encouraging to see the successful transition of several TE POSS-PCU-based organs from the laboratory bench to the clinical bedside. Several more are currently under investigation, including heart valves, skin tissue and other cartilaginous organs such as nose and ear (Figures 7.5 and 7.9). Taken together, POSS-PCU appears highly advantageous, being immunogenically inert while providing nanostructural anchorage points for cellular attachment, proliferation and differentiation. The next section will provide a more in-depth insight into the features of nanocomposite materials to explain the underlying mechanisms of physical induction of cell fate.

Nanocomposites explained—the best of both worlds

Composite materials consist of two or more components of different classes. Nanocomposites consequently consist of two or more components with at least one material dimension below 100 nm. Although reinforcement of composites at the microscale

Figure 7.7 A POSS-PCU ilio-femoral bypass graft transplanted into a human patient. The POSS nanoparticles enhance the endothelialization potential of POSS-PCU grafts to optimize antithrombogenic properties.

(microcomposites) has already been shown to improve mechanical properties, mixing of the starting material with fillers at the nanoscale (nanocomposites) is postulated to have characteristics unanticipated by conventional laws of physics due to the quantum confinement effect¹³⁶ which maintains that the band gap width (which determines the energy needed to promote an electron from the valence to the conduction band and thus is proportional to the potential energy that can be emitted on the electron's return to the valence band) is inversely proportional to the particle's size. This quantum phenomenon underlies the principle that when a certain size (usually <10 nm) is reached, energy levels exist not in continuous states but in discrete quanta, thus supporting the theorem of size-dependence. This can be attributed to the nanoparticle's surface properties and interfacial

Figure 7.8 Comparison of compliance profiles of native arteries (red) with native veins (blue), commercially available vascular replacement grafts (Dacron, dark green; PTFE, light green) and POSS-PCU grafts (black). POSS-PCU grafts show viscoelastic properties similar to those of native arteries.

interactions, as with decreasing dimensions surface area-to-volume ratio increases exponentially, allowing for substantially more reactivity between particle surface molecules and polymeric matrix. Such minute dimensions permit tremendous interfacial contacts between the nanoparticle and the components of the polymer matrix, leading to the aforementioned synergistic improvements of the composite material.

Nanocomposite materials can be classified into biological,¹³⁷ synthetic¹³⁸ or hybrid¹³⁹ materials, with synthetic nanocomposites seemingly dominating the biomedical market. POSS nanoparticles are hexagonal nanocages of roughly 1.5 nm in diameter and can interact with the polymer matrix in all three dimensions.

Polyhedral oligomeric silsesquioxane

First introduced into the biomedical field as an alternative, more biocompatible breast implant material in the 1960s, POSS has risen considerably in global popularity ever since.^{140,141} This is because of its unique 3D cage structure consisting of Si-O and Si-C bonds which can serve as nano-sized building blocks in the manufacture of unique and precisely controlled hybrid materials.^{142,143} POSS is a highly versatile member of the silsesquioxane family and may be shaped into ladder structures, cage and partial cage structures. Nanocomposite materials incorporating POSS are particularly well suited for biomedical applications due to their biostability and degradative resistance, which is due to shorter bond lengths and strong intermolecular forces leading to a strong framework.¹⁴⁴

POSS is regarded the smallest possible silica particle, with an overall diameter of 1.5 nm including the R groups.¹⁴⁵ It has an extraordinary potential to succeed both in scientific, biomedical

and commercial terms due to several synergizing factors: (a) POSS is inherently versatile, thus customizable, due to the ability to attach any chemical moieties to the organic vertex groups (R), (b) the manufacturing process with yields of up to 90% and more is straightforward, facilitating large-scale production, (c) the raw materials are inexpensive, thereby making commercialization economically beneficial with a multitude of possible applications ranging from packaging over inert material coatings to biomedical system enhancements,^{129,136,146} and (d) its rigid inorganic core renders the POSS molecule chemically and thermally stable. This 'self-protection' property of POSS is increasingly exploited for biomedical purposes to create an ideal and dually active biosynthetic interface combining both antithrombogenicity and amphiphilicity.^{147,148} Antithrombogenicity is a principally important feature of cardiovascular graft materials because thrombo-occlusive events with subsequent early graft failure represent the main limiting factors for successful vascular bypass procedures. Amphiphilicity (i.e. the state of being simultaneously hydrophilic and lipophilic) is postulated to be of great exploitable significance

within the field of regenerative medicine by rendering the material highly versatile and enhancing cellular attachment by providing a suitable interface.^{149,150}

Conclusion – Are we there yet?

Recent high profile in-human transplantations of our scaffold have underlined its superb biointegrational ability as well as given credence to the clinical translational potential of laboratory implementation. This chapter has summarized the parameters important for scaffold fabrication and tissue regeneration that seem to underlie the elucidation of the ideal combination of scaffold architecture, mechanical properties and cellular integration.

Decades of research into TE scaffolds have focused on recreating as much as possible various human body parts, frequently using biologically derived biomaterials. The development of the novel and completely synthetic POSS-PCU nanocomposite scaffold and its successful clinical application as a regeneration scaffold raises the question whether or not the scientific community has inadvertently built too restrictive walls in order to mimic as closely as possible the human body, including all its imperfections, which ultimately led to the initial requirement for TE strategies. Thus, instead of attempting to recreate imperfections, perhaps we need to shift our focus and the scientific community should start again with a tabula rasa to re-evaluate the importance of different components and the functions of our organs and tissues.

CHAPTER 8

Skin structure

Anthony Barker

NSW Rotation Plastic Surgery Registrar, Sydney, Australia

The skin is the largest organ in the body, covering around 2 m² in an average adult. It is imperative for barrier protection of the host and to prevent water loss. The skin also plays important roles in initiating immunological defence, thermoregulation and metabolism. The aesthetics of the skin and hair appendages are often overlooked as a function, but these provide the building blocks for social interaction.

This chapter will outline the structure of the skin and its functions. The development of the skin will be traced from its origin in the embryo to the maintenance of homeostasis in the mature adult. An understanding of the basic structure of skin gives clarity to the impact of debilitating skin diseases that affect the components of skin, while stem cell research provides hope that novel cures await.

There are three components to skin: the epidermis, dermis and hypodermis. The epidermis is stratified into four layers:

- the stratum basale;
- the stratum spinosum;
- the stratum granulosum; and
- the stratum corneum.

A fifth layer (stratum lucidum) acts to prevent shearing in thick-skinned areas, such as the hand, between the stratum granulosum and stratum corneum.

The stratum basale is adherent to a basement membrane – the junction between dermis and epidermis – and consists primarily of keratinocytes. Melanocytes (pigment cells), Merkel cells (light touch) and Langerhans cells (antigen-presenting cells) are also found at this level.

The keratinocytes go through the process of proliferation and then differentiation in the stratum spinosum and then granulosum. The terminally differentiated keratinocyte (now referred to as the corneocyte) is stripped of its nucleus to provide the tough protective layer of skin in the stratum corneum. These cells slough off and regenerate from the stratum basale to replenish the reservoir of corneocytes.

The dermis is composed of only two layers: the papillary dermis and reticular dermis. The papillary dermis lies deep to the basement membrane. As its name implies, it is undulating

with the rete ridges of the epidermis. The straight layer deep to this is the reticular dermis, which is primarily composed of elastin and collagen dermal matrix. The appendages to the skin traverse the two structural layers, with the base of the hair follicle, sebaceous glands, sweat glands, vascular supply and lymphatics lying within the dermis (Figures 8.1 and 8.2).

The blood supply to the skin and its appendages is divided into two horizontal plexuses. The upper lies at the level of the papillary dermis, whereas the lower lies at the dermal–hypodermal junction. The upper plexus arterioles divide into capillary loops which supply nutrients to individual dermal papilla (see Hair).¹ Flow between the two plexuses occurs through paired arteriole/venous communications. In addition to nutrient supply to the skin, thermoregulation is aided by the horizontal plexus system. Tactile and nociceptive nerve endings are found in the dermis and all layers of the epidermis² with Meissner corpuscles (light touch receptors) within the papillary dermis. Nerves not only feedback sensory information, but also have been shown to contribute to epidermal homeostasis.³ Skin that has lost nervous innervation is irregularly thin in comparison to the innervated skin.

Epidermal structure and differentiation

The morphology of the epidermis is well understood; however, the molecular process that controls cellular renewal and differentiation are the subject of ongoing research. The basal keratinocytes undergo a process of proliferation and then differentiation to form the four layers. Epidermal stratification relies on two methods: detachment from the basal membrane – known as delamination – and asymmetric cellular division, where the daughter progenitor cell is pushed suprabasally.⁶

The cuboid structure of the stratum basale morphs into the stratum spinosum with the addition of a spinous process to the cell. The transition to the stratum granulosum includes the formation of lamellar bodies (LB) in the cytosol of the keratinocyte. These LBs excrete lipid precursors into the intercellular

matrix, while dense cross-linked proteins engulf the cell membrane. The nucleus and organelles of the cell undergo apoptosis and the skeletonized body remains as the terminally differentiated keratinocyte takes its final form as a flattened polyhedron corneocyte. These two features form the basis for the formation of the barrier membrane.⁷

Figure 8.1 Skin structure and appendages of the dermis and epidermis. Source: Bhushan *et al.*, 2010.⁴ Reproduced with permission of Elsevier.

Figure 8.2 Epidermal layering of keratinocytes with the location of melanocytes and Langerhans cells. Source: Hoath and Leahy, 2006.⁵ Reproduced with permission of Elsevier.

The morphogenesis from basal keratinocyte to barrier-protecting corneocyte takes approximately 14 days. It is a further 14 days before the squame is sloughed from the outer layer. The presence of keratin-5/keratin-14 (K-5/K-14) followed by the replacement with keratin-1/keratin-10 (K-1/K10) marks early differentiation, while the formation of loricrin, fillagrin and involucrin are indicative markers of terminal differentiation.^{7,8}

Homeostasis of the skin relies on multiple regulatory pathways that share commonality with those that are also involved in embryogenesis of the epidermis. At the heart of the process are p63 and Notch signalling.

p63 is the key regulator in determination of epidermal lineage (see Embryology) as well as basal proliferation and differentiation. The dominant epidermal isoform is deltaNp63.⁹ This isoform has important roles in shaping the structural properties of basal keratinocytes, while also signalling the proliferation and then differentiation of the basal keratinocyte. Both integrins and desmosome expressed on the keratinocyte membrane are regulated by p63. They are necessary for both cell-cell and cell-basement membrane adhesions – the structural integrity of the skin is compromised if these unions cannot be formed.¹⁰ p63 is the initial signal for expression of K-14 in basal keratinocytes; without this input, the ectodermal cells would remain in their non-proliferative embryological keratin-8/keratin-18 state.¹¹

The Notch pathway is antagonistic to p63, promoting differentiation and suppressing p63's proliferative potential when highly expressed. This regulatory balance is the basis for homeostasis in adult skin, where the equilibrium exists between the requirement of proliferation and cellular differentiation of the layers.^{12, 13} The Notch pathway is necessary for terminal

differentiation of mature basal keratinocytes and for release of the cells from the basement membrane.⁶ Immature daughter cells of basal progenitor cells, however, will not undergo terminal differentiation in the presence of Notch until reaching maturity.¹⁴ p63 and Notch's role in proliferation and differentiation allow the skin to continually renew its function as a barrier to the external environment.

Barrier formation

The combination of stratification and differentiation forms the skin's barrier function. The final process of cornification results in a membrane that provides rigidity, prevents water loss and gives protection to the external environment. This is achieved through cross-linked proteins that surround the now keratinized core and an extracellular lipid mesh that seals the corneocytes. The resulting hydrophobic environment that surrounds the corneocyte is referred to as the corneocyte envelope. Desmosomal structures (termed corneodesmosomes) and the lamellar lipid network bind the corneocytes together to form the skin barrier.

The primary lipids of the corneocyte envelope are ceramides, fatty acids and cholesterol, which are formed in the Golgi apparatus in the granular layer. These lipids are stored in lamellar bodies before being released into the extracellular environment during cornification, where enzyme modification results in the lipid structure. Concurrently, the production of profilaggrin by the keratohyalin granules in the granular layer is the precursor to filaggrin. Filaggrin condenses the keratin in the cell to give the corneocyte its unique flattened polyhedral shape. The resulting filaggrin matrix constitutes 80–90% of the epidermal protein weight.¹⁵ Terminal protein markers of differentiation, loricrin and involucrin, have important structural roles in the corneocyte envelope. Involucrin is often described as the scaffold to which other proteins cross-link; it also provides covalent bonding with the external lipid network.¹⁵ Loricrin is cross-linked with small proline-rich proteins (SPRs) before incorporation beneath the plasma membrane. Transglutaminases synthesize these proteins into cross-linked peptides; the strength of the corneocyte envelope is reliant upon the isopeptide bonds formed by the transglutaminases.¹⁵

Basement membrane

The basement membrane is the acellular divide between the epidermis and dermis. The primary function of this membrane is to resist shear forces between the epidermis and dermis, while creating a physical bond between the two structures. In addition, the basement membrane plays important roles in establishment of keratinocyte migration in the epidermis and polarization for keratinocyte cell division.¹⁶ Structurally, the basement membrane is similar to the mature skin by the end of the first trimester¹⁷ and is reliant upon epithelial–mesenchymal interaction for its development.^{18,19}

The four components of the basement membrane are: the plasma membrane of the keratinocytes, the lamina lucida, lamina densa, and sublamina densa.²⁰ Integrins link hemidesmosomes on the plasma membrane of the basal keratinocytes to the basement membrane.¹⁹ The thin lamina lucida is composed of laminin-332 and laminin-511 (previous nomenclature was laminin-5 and laminin-10, respectively), while collagen IV along with nidogens and perlecan are predominant in the lamina densa that provide mechanical strength.¹⁶ Bridging of collagen IV with nidogens and perlecan join the lamina densa to the laminin scaffold of the lamina lucida.²¹ Finally, collagen VII in the sublamina densa extends to underlying stromal tissue through anchoring fibrils that insert into plaques in the reticular dermis. This is the strongest point of epidermal–dermal adhesion within the basement membrane, followed by the hemidesmosome attachments from keratinocytes.¹⁷ Fibroblasts and keratinocytes are responsible for the deposition of collagen IV and VII along with regulation of the other basement membrane components from these key cells.¹⁹

Dermis

The dermis lies deep to the epidermis and the basement membrane. It is composed of the undulating papillary dermis and the straight reticular dermis.

The papillary dermis interdigitizes with the rete ridges of the epithelium at the dermal–epidermal junction. It serves to increase signalling between the layers and provide nutrient supply.²²

The predominant reticular dermis houses the extracellular matrix of collagen, elastin, glycoaminoglycans and adipocytes. The elastin fibres are composed of an elastin core surrounded by microfibrils of primarily fibrillin.²³ These fibres in the reticular dermis are thick and arranged in parallel to the skin surface. This arrangement contrasts with the thin perpendicular elastic fibres (elastin fibres) of the reticular dermis. The elastin fibres give the skin its characteristic resilience to deformity.²³

At least half of all collagens are expressed in the skin, with the fibril-forming collagens I and III being the most abundant in the dermis, lying parallel to the skin surface (in the reticular dermis).²¹ The collagen fibrils provide a scaffold for other proteins to attach to, which confers tensile strength to the skin.²¹

Hyaluronic acid, a glycosaminoglycan, is responsible for water retention in the dermis, conferring the skin's plump fullness when saturated. Fibroblasts in the dermis are primarily responsible for the synthesis of the extracellular matrix. Below the dermis lies the hypodermis, with the reservoir of subcutaneous tissue that provides the stored energy for development in adipocytes.

Embryology

The embryonic development of the epidermis is from the ectoderm with signalling from the mesenchyme. The ectoderm is evident from embryological day 21, where it consists of a single proliferative layer. Bilayer formation with the periderm occurs from day 55 before the formation of an intermediate layer at day 70. Four-layer stratification is evident at day 90, including the stratum corneum – indicative of late terminal differentiation (Figure 8.3).²⁴ The maturation of the stratum corneum is necessary for the assault on the skin from the extra uterine environment. With the formation of the stratum corneum, the periderm is sloughed, allowing the skin to form its mature barrier protection. The immediate function of skin in the neonate is to ensure water retention to prevent potentially lethal dehydration. By the end of the first month post partum, the transepidermal water loss (measured in g/m² per h) is similar to that in an adult. In addition, the acidity of the skin increases by the end of the first week post partum, which enhances the mechanical and immunological defence mechanism of the skin.²⁵

Figure 8.3 Ectodermal lineage selection promotes stratification of the newly formed epidermis. The protective surface of the periderm allows the immature epithelium to form. Hair follicle formation originates from the hair placode adjacent to the interfollicular epithelium (IFE). Some of the many stem cells markers of this region are indicated in the left corner. Source: Benitah and Frye, 2012.³³ Reproduced with permission of Elsevier.

Skin appendages

Hair

Hair serves multiple purposes, including thermoregulation, sebum and sweat dispersion as well as important social functions. Human hair is composed of pigmented terminal hairs – primarily found on the scalp – and the universally found vellus hairs.²⁶

The structure of the pilosebaceous hair follicle from deep to superficial is the dermal papilla, followed by the basement matrix that provides the growth front for the hair follicle. The regenerative capacity of the hair follicle is stored in the bulge zone, which is activated when the follicle grows. The sebaceous gland opens distally to the bulge with the erector pili muscle attaching at this level. The isthmus is the bridge between the hair bulge and the transition zone before the hollow infundibulum continues out into the interfollicular epithelium (IFE) (Figure 8.3).

The hair shaft is formed from dividing cells of the bulge, which migrate to the base of the shaft – now termed matrix cells – before stratifying into the cells of the hair follicle. The hair follicle is divided into three zones: the outer root sheath (ORS) that maintains its connection with the basement membrane; the inner root sheath (IRS); and the hair shaft, all of which are composed of terminally differentiating keratinocytes formed from the matrix cells.²⁷

Pigmentation of the hair shaft comes from melanin (eumelanin for black and pheomelanin provides red colouration). Melanin is released from hair follicle pigmentation units near the dermal papilla. The principal cell of the pigmentation unit is the melanocyte, which is in close proximity to the melanin-receiving keratinocytes.²⁶

Hair follicles form from signalling between the developing mesenchyme and epidermis. The initial hair placode forms in the IFE and projects into the dermis. Signalling from the placode forms a dermal ‘condensate’ of fibroblast cells known as the dermal papilla.^{26–29} The downward-growing placode (soon to be hair bulb) and the dermal papilla constitute the growing hair follicle. The initial signal for hair follicle formation comes from the Wnt/beta-catenin pathway, which is evident from knockout of beta-catenin which universally affects hair follicle formation in the murine model.^{26,27} The regular spacing hexagonal spacing of new hair follicles in the epidermis is evidence that signalling from the hair follicle has an inhibitory effect on where the next follicle is placed.²⁷ This ensures maximum resource distribution between developing hair follicles.

The necessity of the hair follicle to shed and renew requires the ability of the matrix to undergo cell cycling. Matrix cells proliferate through the anagen phase, resulting in the growth of the hair shaft (Figure 8.4). During catagen, the apoptosis of these cells result in shrinkage of the dermal papilla until it is level with the regenerative cells of the bulge.²⁶ Telogen is the resting phase of the cell cycle, where the matrix cells lie dormant until signalled to once again undergo proliferation. With age, the length of time for the cells to enter anagen increases, thereby decreasing cycling frequency.²⁶

Figure 8.4 Hair follicle growth originates in early anagen whereby the bulge cells are stimulated to multiply. These cells migrate to the matrix initiating the growth phase of the hair follicle in late anagen. Catagen signals the apoptosis of the matrix and the shedding of the hair shaft. During telogen, the hair follicle is refractory to growth until the dermal papillae returns the level of the bulge cells. Source: Goldstein and Horsley, 2012.³⁰ Reproduced with permission of Springer.

Sebaceous glands

Sebaceous glands empty sebum – a dense lipid-filled mixture – into a secretory duct in the junctional zone of the hair follicle. The waxy sebum prevents water loss from the IFE and assists in thermoregulation.³¹ The sebaceous gland is a sac-like structure lined with keratinocytes that specialize to sebocytes. The sebocytes differentiate concentrically until the core undergoes cell death, resulting in a central core of necrosis. The lysis of the necrotic cells results in the release of lipids into the secretory duct usually associated with the hair follicle. The sebaceous gland is formed in the human embryo at the 13th to 14th week of gestation; however, it is not until puberty that the sebaceous gland enlarges in response to sex hormone stimulation.

Stem cells

Stem cells are the focus of recent investigation into the regenerative capacity to maintain homeostasis of the IFE, hair follicle and sebaceous gland. Stem cells are defined by their ability to

undergo lineage commitment. The cyclical process of epidermal renewal in the IFE, hair follicle and sebaceous gland suggests that a single cell could be responsible for lineage renewal. Isotope tracing has identified such cells in the bulge of the forming hair follicle as well as a separate multipotent cell in the upper isthmus. The cells of the bulge undergo their cycle slowly and appear to have the ability to differentiate into cells of the ORS, IRS and hair shaft. They express for the transcription factor Sox9, which promotes the expression of the CD34 cell receptor.³² The multipotent cells of the upper isthmus expressing MTS24 surface marker were traced to IFE, sebaceous gland as well as hair follicle.^{30,32} In addition, Lrig1-positive cells of the transition zone can also be traced to all three epidermal lineages and provide a pool of regenerative cells for the IFE^{30,33,34} (see Figure 8.3).

Whether these stem cell groups function independently, or form from the same multipotent progenitor, remains the focus of research. It is unclear if any of these lineage cells, once terminally differentiated, are able to regress to their original progenitor cell. However, it has been found that the pathways responsible for

morphogenesis have similar roles in homeostasis.^{31,32} Further research in this area will help elucidate the role of stem cells and their potential for wound healing, regeneration of skin appendages and the role of stem cells in cancer.

Fitzpatrick's skin classification

Skin type is commonly classified from type I to type VI based upon Fitzpatrick's skin classification system. American dermatologist TB Fitzpatrick designed the original classification system based on the response of skin to the minimum erythema dose (MED) of UVB. He based skin types I–III on his 1972 study of response to a time-dependent exposure of midday sun in Australians with Caucasian skin type. Type I skin was characterized as skin that burns easily with no appreciable tan at one week post exposure; type II skin burned but formed a light tan at one week; and type III skin had little burn and moderate tan at one week post exposure.³⁵ Subsequent formulation of types IV–VI included pigmented skin. Type IV skin did not burn and tanned at one week, whereas types V and VI are characterized by brown and black pigmented skin, respectively.³⁶

Determination of the Fitzpatrick skin classification is by a series of nine questions scored out of 4 points. These questions are broken into two sections: genetic disposition and sun exposure.³⁷ One criticism of the classification system relates to the subjectivity in issuing the questionnaire. However, several studies have shown that there is a strong correlation between cancer risk and skin type for both non-melanocytic and melanocytic cancer.^{37,38} In addition, skin type is an important determinant in evaluating treatment doses for laser therapy and topical treatments.

Ageing skin

The ageing process of the body is visibly manifested in the skin. Aged skin is characteristically thinner and dry with visible wrinkling, reduced elasticity and abnormal pigmentation.³⁹ The causes can be classified into changes at the cellular or extracellular level. Cellular damage involves mutations to the DNA that have the potential to cause abnormal cell functioning and signalling. Extracellular damage can manifest in protein degradation or reduced synthesis of proteins, importantly collagens I and III in the dermis as well as glycosaminoglycans and proteoglycans.^{39,40} The flattening of the dermal–epidermal junction results in the loss of the papillary vasculature and reduced ability to deliver nutrition to the skin.⁴¹

Epidermal stem cells associated with homeostasis of the skin barrier are unique in the body: the frequency in which they divide and the number of stem cells are maintained through adulthood. These stem cells are not instigators of the ageing process.⁴² The widely accepted cause of ageing is a result of accumulation of reactive oxygen species (ROS).³⁹ The ROS cause damage to the

cell's DNA as well as the mitochondria, which can result in a shift to glycolytic anaerobic metabolism.⁴³ This shift increases the accumulation of oxidative free radicals that can result in the degradation of collagen through the indirect stimulatory effect of ROS on matrix metalloproteinase (MMP) production.³⁹

There are many treatments available to prevent skin ageing. Topical application of coenzyme Q10 is shown to stabilize the mitochondria and help prevent the oxidative effects of the glycolytic pathway.⁴³ To improve the skin texture and density, topical application and nutritional intake of antioxidants have proven efficacy.⁴⁴ Preventative measures for premature ageing of the skin involve the avoidance of UV exposure and smoking. UV has a similar destructive pathway on skin as ageing with the promotion of MMP production, resulting in the breakdown of collagen.³⁹ The skin of smokers is dry and dull with associated wrinkling of the mouth from the pursed lip used for smoke inhalation. Smoking increases the production of collagenase while reducing its blood supply, resulting in the characteristic smokers' skin.³⁹

Clinical diseases

Disease of the skin manifests at all structural layers of the skin. The following review of skin diseases gives examples of how the molecular structure of the skin can be compromised.

Connective tissue diseases

Ehlers–Danlos syndrome is a heterogeneous group of diseases that affect the collagenous network of the dermis. The clinical presentation is of weak, hyperelastic and easily bruised skin. Ehlers–Danlos syndrome results from deficits in the production or quality of collagen fibrils I, III and IV. These deficits are caused by mutations in the genes that code for the collagens or their associated structural proteins or production pathways.²¹

In contrast, the appearance of skin in the rare disorder cutis laxa is loose tissue that gives an appearance of premature ageing. Cutis laxa is caused by deficits in the production of elastic fibres, which result from a heterogeneous group of mutations that affect either the composition of elastin or the microfibril, which disrupt the elastic fibre composition. In autosomal recessive cutis laxa, the disorder not only affects dermal tissues, but also causes cardiovascular deficiencies and pulmonary emphysema.⁴⁵

Marfan's syndrome is known for its multiple and severe cardiac manifestations caused by a mutation of the gene for fibrillin-1 that results in both morphological changes to the microfibril and an increase in transforming growth factor beta (TGF- β) signalling. TGF- β stimulates the increased production of collagen and the resultant skin is thin with increased laxity.^{21,45}

Disease of the basement membrane and epidermis

Epidermolysis bullosa is categorized into inherited and autoimmune disease. The disease is characterized by bullous blisters that occur either in the epidermis or the basement membrane.

(c) Cutis laxa. Source: Tassabehji *et al.*, 1998.⁴⁷ Part (c) reproduced with permission of Oxford University Press.

Epidermolysis bullosa is caused by weakening of the dermal–epidermal attachment of keratinocytes at the basement membrane. There are three types of inherited epidermolysis bullosa: epidermolysis bullosa simplex (EBS), junctional epidermolysis bullosa (JEB) and dystrophic epidermolysis bullosa (DEB).⁴⁶

EBS forms blisters at the junctional layer due to mutations in the gene coding for keratinocyte proteins K-5 and K-14, which are essential for cellular connectivity and structure.

JEB is a result of mutations in collagen XVII or laminin-332, which link keratinocytes to the basement membrane in the lamina lucida. The most severe form is the Herlitz variant where the absence of laminin-332 results in ulcerative erosions. Without epithelial regenerative capacity, uncontrolled fluid loss is lethal within the first year of life.

DEB is inherited as the severe autosomal recessive form or the mild dominant form, affecting collagen VII formation and the adhesion of the anchoring fibrils into the sublamina densa. The resultant chronic wounds are healed by extensive fibrosis formation (Figure 8.5).

Two autoimmune diseases have the same clinical appearance as epidermolysis bullosa: bullous pemphigoid and epidermolysis bullosa acquisita. In bullous pemphigoid IgG autoantibodies target collagen XVII, which is a transmembrane protein responsible for keratinocyte adhesion to the basement membrane. The IgG autoantibodies in epidermolysis bullosa acquisita attach to the binding sites of collagen VII, preventing adhesion to laminin-332 and thereby stopping adhesion of the anchoring fibril to the basement membrane.⁴⁶

The previously untreatable condition of epidermolysis bullosa is the focus of multiple treatment pathways from protein replacement to gene modification and stem cell transplantation,⁴⁸ which give hope for treatment options for these debilitating and potentially lethal diseases.

Current research in recessive DEB has achieved synthesis of collagen VII via the introduction of fibroblasts in the preclinical murine model, with improved strength at 100 days post implantation.⁴⁹ Another potential treatment method involves the injection of collagen VII directly into the wound sites: at four

weeks post injection in mice there is improved integrity of the dermal-epidermal junction.⁵⁰ Finally, mesenchymal stem cells derived from bone marrow were used in human trials to stimulate the production of collagen VII.⁵¹ The progress of this and other treatment options for the spectrum of debilitating skin diseases will provide new hope for those suffering from the multiple heterogeneous disorders of the skin.

CHAPTER 9

Melanoma

Carlo Riccardo Rossi and Antonio Sommariva

Melanoma and Sarcoma Unit, Veneto Institute of Oncology IOV, IRCCS, Padova, Italy

Epidemiology

Over the past four decades, melanoma has shown a consistent increase in incidence in White populations, becoming one of the most frequent cancers in light skin populations. The incidence rate of this disease varies widely in relation to race, occurring much less commonly in Black, Asian, or Hispanic populations. Although White and non-White populations have similar risks of developing plantar melanoma, non-White populations have a greater risk of developing non-cutaneous melanomas (e.g. mucosal). Melanoma is now regarded as the fifth most common cancer in men and the sixth most common cancer in women in the United States. The highest recorded incidence of melanoma worldwide is in Australia and New Zealand, with an incidence of 27.3–55.8/100 000 for males and 23.4–41.1/100 000 for females. In the USA, the incidence rate is 19.4/100 000 for men and 14.4/100 000 for women. In European countries, the incidence rates are lower, being highest in Switzerland and Scandinavian countries. Moreover, they show a north to south gradient, with the highest rates in northern countries. This is probably related to both the increased protection against the sun rays of the pigmented skin of southern Europeans and the different pattern of sun exposure (chronic in southern Europeans, intermittent in northern Europeans).¹

In many countries, early detection of primarily thin melanomas and improved survival rates have been observed, especially in young females. However, in most countries the incidence of thick melanomas remains constant or continues to increase, especially in the older age group. Melanoma occurs approximately 1.5 times more often in men than women, and prognosis is slightly better for women, considering other prognostic factors. The anatomic distribution of melanoma is sex-dependent, occurring more often on the trunk in males and on the arms and legs in women.

Melanoma can occur at any age but is rare before the age of puberty. The median age at the time of diagnosis ranges between 45 and 55 years, with an increase in incidence after the age of 25 until 50 years.

Risk factors

Current considerations in the epidemiology of melanoma showed that melanoma results from an unidentified interaction between mutations in various genes and constitutional and/or inherited factors combined with environmental factors, mainly solar ultraviolet radiations.^{2,3} Exposure to UV is the most important environmental factor predisposing to melanoma in susceptible populations. It is reported that people incurring severe burns in childhood appear to be at higher risk for the development of melanoma in later age. Iatrogenic exposures, such as immunosuppressive agents and non-steroidal anti-inflammatory drugs, have been studied as additional environmental factors. Well-known host risk factors, such as melanocytic naevi on the skin, skin type, family history and genetic susceptibility, have been validated as risk factors in large-scale association studies. Patients with more than 100 naevi or giant naevi (>20 cm) have an increased risk of melanoma. In addition, genome-wide association studies have revealed genetic loci that underlie the genetic susceptibility of melanoma, some of which are related to known risk factors. Mutations or epigenetic silencing of the cyclin-dependent kinase (CDK) gene are linked to 20–40% of familial melanoma. Other genes involved in familial melanoma carcinogenesis include *CDK4*, xeroderma pigmentosum genes and melanocortin 1 receptor gene (*MC1R*). Activating mutations in the *BRAF* gene have been discovered in over two-thirds of melanomas. Melanomas on skin without chronic sun-induced damage had frequent mutations in *BRAF*; in contrast, acral and mucosal melanomas as well as skin melanomas with chronic sun damage are frequently characterized by *Kit* mutations. These mutations are responsible for cancer cell behaviour through mechanisms that are still undefined.

Clinical diagnosis

Melanoma usually appears as an irregularly pigmented skin lesion with an irregular border and a tendency to grow or change over time. Melanomas arise mostly de novo, just occasionally

within a congenital or acquired naevus. In the past, they were often diagnosed in advanced stages as large, ulcerated or vegetating lesions. The need to detect melanomas at an early stage of disease led to the development of the ABCDE criteria, an acronym for asymmetry, border irregularity, colour alterations, diameter >6 mm and evolution. Not only are these simple criteria intended to allow both patients and non-dermatologist healthcare professionals to differentiate common melanocytic lesions from suspicious pigmented lesions, they are also a useful tool for dermatologist in guiding the decision to perform a biopsy. The sensitivity of clinical diagnosis by physicians with experience in differential diagnosis of suspected cutaneous lesions is about 70%. Dermoscopy, also known as epiluminescence microscopy, improves the diagnostic accuracy of melanocytic lesions. Dermoscopy, when adopted by experts, increases the sensitivity of clinical diagnosis up to 89%, reducing the number of negative biopsies. In high-risk patients (e.g. with atypical mole syndrome), a follow-up examination with digital dermoscopy and total-body microphotography is also helpful in detecting early changes in lesions or in discovering new atypical lesions. In patients with a previous melanoma, the risk of harbouring a second melanoma is significant and implies scheduled examinations of the skin at regular intervals for detecting second tumours or skin metastasis.

Biopsy

In the presence of a skin lesion with a clinical suspicion of melanoma, the patient is referred for an excisional biopsy. The biopsy of a suspected lesion is a simple procedure, practicable under local anaesthesia, on an outpatient basis. The procedure consists in complete removal of the lesion with about 1–2 mm of surrounding healthy skin up to the subcutaneous fat. During the procedure, care should be taken to avoid causing trauma or injury to the specimen, which could compromise a correct histopathological analysis. The choice of incision lines of the biopsy must take into account the further excision of the skin involved, preferring longitudinal incisions in the biopsy of the limbs while trying to minimize as much as possible the need of skin grafts. Excisional biopsy allows an accurate histopathological diagnosis, providing all the histological parameters necessary to formulate a prognosis and to plan the best therapeutic strategy. However, excision of the whole lesion may not be indicated in some cases: for example, in the presence of a large lesion, or in the case of proximity of the lesion to difficult areas (subungual) or important structures (eye, nose and ear). In these circumstances, punch or incisional biopsy should be considered. In the incisional or so-called 'punch' biopsy, only a full-thickness portion or a pill of the most suspected portion of the lesion is removed. Superficial biopsies, 'shave biopsy', and any type of laser or diathermocoagulation should be avoided, as they do not allow an accurate pathological staging and can lead to a significant delay in diagnosis of any potentially malignant lesions.

Histology

The histological diagnosis of cutaneous melanoma is not always easy and it would be desirable for an expert pathologist in the diagnosis of pigmented lesions of the skin to perform the analysis. In doubtful cases, morphology may indicate the use of immunohistochemical surveys (such as HMB-45, Ki-67, p16) and fluorescence *in situ* hybridization (FISH) techniques, the reading of which requires experienced operators. Histologically, invasive cutaneous melanomas are divided into four major subtypes. These are based on growth pattern and location, and are categorized as follows:

- superficial spreading,
- nodular,
- lentigo maligna, or
- acral lentiginous.

A fifth subtype is also defined: desmoplastic melanoma. In general, the histologic subtype of melanoma is not a major factor in determining prognosis, but some histologic subtypes are more likely to be detected at an advanced stage, thus indirectly affecting prognosis. Melanoma originates from the proliferation of melanocytes in the basal layers of the epidermis, which tend to expand radially and later invade deep into the dermis.

Superficial spreading melanoma is the most common (70%), can occur in any location and is characterized by a radial growth associated in the later stages to a pattern of vertical proliferation. Nodular melanomas, occurring in about 15%, are characterized by an exception to this pattern, with an exclusive vertical growth not accompanied by radial growth. Because of its invasiveness, it is usually diagnosed at a more advanced stage of invasion. Lentigo maligna accounts for about 10% of melanomas and is characterized by onset in old age, in chronically sun-exposed skin sites with a history of slow growth. These lesions are characterized by a long phase of intraepithelial growth and for this reason are considered a lesion with a better prognosis, though always remaining linked to the degree of invasion. Acral lentiginous melanoma is the less common type (5%); it is classified mainly for its site of origin (subnail bed and the palmar and plantar surfaces) rather than for histological features, which are similar to melanoma of the mucous membranes. Diagnosis is often delayed, especially for subungual forms often confused with posttraumatic haematoma. Among the rarer variants, desmoplastic melanoma has non-typical melanocytic cells and is characterized by a significant deposition of collagen, which hinders differential diagnosis with other fibrohistiocytic tumours or schwannomas.

The vertical growth phase is the tumourigenic phase in which the melanoma acquires the ability to metastasize. Morphologically, it is characterized by the presence of an expansive nodule larger than the intraepidermal component and/or by the presence of mitotic figures in the invasive component. In 1969, Clark formulated a histological classification with a prognostic value for melanoma based on the level of invasion in the anatomical layers of the skin, highlighting for the first time the prognostic significance of the degree of invasion (Table 9.1). However, the

Clark system has proven to be a source of significant variability among pathologists, especially in stages III and IV, thereby losing its prognostic relevance in more recent years.

In 1970, Breslow described a more objective method of classification, based on the measurement in millimetres of the vertical thickness of the tumour.⁴ The Breslow thickness is measured from the granular layer or, if the lesion is ulcerated, from the bottom of ulceration, up to the point of maximum infiltration. This classification system has been shown to be more reproducible among pathologists, showing an excellent correlation with mortality. Prognosis tends to become progressively worse in logarithmic function, up to 8 mm where it

reaches a plateau, beyond which never reaching 100% mortality. Among histological features assessed for their prognostic value, the presence of ulceration and/or mitosis are considered the most important, correlating in a totally independent way to the prognosis. Ulceration is defined as the absence of intact epithelium overlying the melanoma. Patients with ulcerated melanomas have a worse prognosis even among those with regional nodal metastasis. Ulceration represents a phenotypic marker of aggressive tumour biology and predicts a greater propensity for invasion and metastasis.

In the same way, the mitotic index, although more recently validated, has been recognized as an important histological parameter in melanoma, especially in melanomas with Breslow less than 1 mm. The mitotic index is expressed as the number of mitoses per mm² in the invasive component of melanoma, rated from the areas with increased mitotic activity ('hot spots') after extending the count to an adjacent area of 1 mm². Several other prognostic factors have been recognized, such as tumour-infiltrating lymphocytes, regression, lymphatic invasion and microsatellitosis, but they showed minor effects on prognosis.

Table 9.1 Melanoma invasion expressed as Clark level

Level I	Confined to the epidermis
Level II	Invade but not fill or expand the papillary (superficial) dermis
Level III	Fill and expand the papillary dermis with extension to the papillary–reticular dermal interface
Level IV	Infiltrate into the reticular dermis
Level V	Infiltrate into the subcutaneous fat

Table 9.2 TNM staging categories for cutaneous melanoma

T category	Thickness (mm)	Ulceration status/mitoses
Tis	NA	NA
T1	≤1.00	a: Without ulceration and mitosis <1/mm ² b: With ulceration or mitosis ≥1/mm ²
T2	1.01–2.00	a: Without ulceration b: With ulceration
T3	2.01–4.00	a: Without ulceration b: With ulceration
T4	>4.00	a: Without ulceration b: With ulceration
N category	Number of metastatic nodes	Nodal metastatic mass
N0	0	NA
N1	1	a: Micrometastasis ^a b: Macrometastasis
N2	2–3	a: Micrometastasis ^a b: Macrometastasis c: In-transit metastasis or satellites without metastatic nodes
N3	4+ metastatic nodes, or matted nodes, or in transit metastases or satellites with metastatic nodes	
M category	Site	Serum LDH
M0	No distant metastasis	NA
M1a	Distant skin, subcutaneous or nodal metastases	Normal
M1b	Lung metastases	Normal
M1c	All other visceral metastases	Normal
	Any distant metastasis	Elevated

NA, not applicable; LDH, lactate dehydrogenase.

^aMicrometastases are diagnosed after sentinel lymph node biopsy. Macrometastases are defined as clinically detectable nodal metastases confirmed pathologically.

Staging

The most widely used staging system for melanoma is based on the analysis of the American Joint Committee on Cancer (AJCC) melanoma staging database (Tables 9.2 and 9.3).⁵ This staging system has recently been updated with important modifications with respect to the previous edition. Major changes include mitotic rate that replaces level of invasion (Clark) as primary criterion for defining T1b melanomas. Moreover, patients with microscopic nodal disease, regardless of extent of tumour burden (also including metastasis detected by immunochemistry), are classified as stage III. For distant metastasis, the most determinant factors for prognosis continue to be the site (non-visceral versus lung versus visceral) and an elevated serum lactate dehydrogenase (LDH) level. Outside the histological microstaging, no consensus has been reached on the value of additional staging examination for detecting metastatic melanoma and on their applications after a primary diagnosis or during follow-up.⁶

Today, 50–70% of melanomas are diagnosed in an early stage (stage IA), with a very low risk of recurrence and distant spread. Therefore, it is important to identify which staging investigations are indicated in the different classes of risk. A meta-anal-

ysis performed comparing the usefulness of ultrasound, CT scan, PET and PET-CT in the staging of patients with melanoma concluded that ultrasound is superior to the other methods in detecting metastasis to the lymph nodes, while PET-CT is superior in detecting distant metastases.⁷ It is difficult to draw clear guidelines for examinations that should be used for the staging of patients with melanoma. A general indication is to modulate the examinations in relationship with the risk and/or the presence of metastases. No examination staging should be performed in patients with melanoma *in situ*. For asymptomatic patients with T1 melanomas, clinical examination alone seems adequate for staging and follow-up. Careful skin and lymph node examination excludes other concomitant lesions and is considered sufficient for skin and lymph node metastasis. However, even in this lower risk group, ultrasonography of the drainage basin (or basins) of the primary melanoma is advocated by some for its simplicity, high efficiency, low cost and good tolerability, especially when the examination is performed by an experienced operator. In case of suspicious lymph node on ultrasound investigation, fine needle biopsy, combined with cytology, allows diagnostic confirmation in the vast majority of cases. Very controversial is the role of chest X-ray and abdominal ultrasound in the presence of intermediate risk (T2–T4a), while a certain consensus seems to emerge on the indication for total body CT scan or PET-CT in melanomas at high risk for distant metastasis (T4, ulcerated, mitotic index >1) and/or in presence of lymph node metastases. Finally, among blood tests, an indication for dosage of LDH in patients with distant metastases (or high risk) is widely shared, as LDH levels are able to stratify risk of death in these patients.

^aClinical staging includes microstaging of the primary melanoma and clinical/radiologic evaluation for metastases. By convention, it should be used after complete excision of the primary melanoma with clinical assessment for regional and distant metastases.

Pathologic staging includes microstaging of the primary melanoma and pathologic information about the regional lymph nodes after partial (i.e. sentinel node biopsy) or complete lymphadenectomy. Pathologic stage 0 or stage IA patients are the exception; they do not require pathologic evaluation of their lymph nodes.

Wide excision

Wide excision represents the standard treatment for primary melanoma and has the primary goal of achieving durable local control of disease, minimizing the risk of local recurrence and curing patients with clinically localized melanoma. Wide excision involves removal of a surrounding margin of normal skin, *en bloc* with subcutaneous tissue down to the muscular fascia, which should be excised only if clearly infiltrated. It is a simple surgical procedure, performed in most cases under local anaesthesia, on an outpatient basis and less frequently under general anaesthesia, especially when complex reconstruction techniques are required or a concomitant sentinel lymph node biopsy or lymphadenectomy is planned.

The most important oncological principle is to preoperatively define the healthy margin that must be obtained for adequate surgical resection. The free excision margin should be measured radially from the edge of the lesion or the biopsy scar and should be adjusted according to the thickness of the primary tumour at histological examination. The width of excision margins has been investigated in several randomized controlled trials. Some meta-analysis show no differences in overall survival between

Table 9.4 Recommended excision margin according to melanoma thickness

Thickness	Excision margins
<i>In situ</i> melanoma	5 mm
Breslow ≤ 2 mm	10 mm
Breslow > 2 mm	20 mm

large excisions (3–5 cm) and narrow excisions (1–2 cm), whereas they seem to highlight significant differences in disease-free survival.⁸ On the basis of currently available data, the appropriate excision margins should be tailored on the thickness of primary melanoma as reported in Table 9.4.

Although melanoma *in situ* is considered a non-infiltrating lesion, in some cases a local recurrence can occur; in rare cases, it occurs as an infiltrative lesion with metastatic potential. A margin of 0.5 cm ensures excellent local control. In a particular form of melanoma *in situ*, lentigo maligna type, the lesion appears more extensive microscopically than upon clinical examination. For this reason, a 1 cm margin is advisable in the presence of lentigo maligna, due to the possibility of finding residual foci in the final pathologic assessment when conventional excision is adopted. Despite a close observation of these guidelines, some melanomas *in situ* require multiple excisions to achieve a safe margin, and occasionally split-skin grafts or flaps are necessary for wound closure.

The surgical specimen, including skin and subcutaneous tissue, should always be sent for final histological analysis to detect residual tumour or satellites nodules. For this analysis, it is advisable to send an orientated specimen, which facilitates re-excision if margins are involved or are very close to the tumour. Primary closure can be obtained in the vast majority of cases, sometime after mild mobilization of skin edge from the underlying fascia. Skin grafts or tissue flaps may be necessary for melanomas located in less mobilizable anatomical areas, such as the distal extremities and the scalp. In specific areas (nose, ears, eyelids), extensive demolition by removing portions of the cartilage may be necessary if clearly infiltrated. In these areas, if surgery involves disabling outcomes from an aesthetic and functional point of view, the width of excision can be modulated based on the risk of recurrence. The reconstructive technique should be properly planned and all the cosmetic and functional factors should be discussed with the patient. In these situations, some advocate Mohs micrographic surgery (MMS). MMS is a technique that involves sequential margin excision of skin around the tumour with immediate intraoperative histological margin assessment. MMS provides more a limited margin of excision and is performed, with favourable outcome, mostly in squamous cell and basal cell carcinoma. For melanoma, the presence of potential satellite microscopic disease discourages the use of MMS in infiltrating melanomas. A lower recurrence rate after use of MMS has been reported for melanoma *in situ* but, at this level of evidence, the technique should be performed in selected cases, preferably in the context of clinical trials.

For melanoma of the nail bed and the distal phalanx, recommendations for treatment are not evidence based. In general, for subungual or distal phalanx melanomas ≤ 2 mm thick, generally a 1 cm gross margin from the tumour can be obtained with amputation at the level of the distal phalanx. For more infiltrating melanomas, amputation is indicated at the level of the metatarsal/metacarpal phalanx. The function of the finger involved (first/second finger) can suggest more limited resection and all the pros and cons of radical surgery must be discussed in detail with the patient.

Sentinel lymph node biopsy

The rationale for sentinel lymph node biopsy (SLNB) is based on the hypothesis that the lymphatic spread of metastatic cells from the primary melanoma to the regional lymph nodes is an orderly and definable process. Accordingly, the first lymph node(s) that receives lymphatic drainage from the affected area is considered the sentinel lymph node (SLN), because it is the most likely to contain metastatic disease in that specific lymphatic basin. It follows that successful identification, surgical removal, and careful histologic examination of all SLNs in a patient should provide a more accurate regional nodal staging. A significant percentage (15–20%) of patients with a diagnosis of primary melanoma harbour undetectable metastasis (either clinically or with ultrasonography) in the regional lymph nodes. Micrometastases, if left untreated, will become clinically evident with time, thus motivating the need to discover this occult disease at an early stage. The impact on survival of SLNB in melanomas remains unknown, however. The Multicenter Selective Lymphadenectomy (MSLT-I) trial randomized 1347 patients with melanomas 1.2–3.5 mm thick to undergo wide excision alone or wide excision with SLNB. The results of this study showed that the 5-year melanoma-specific survival rates were not significantly different for the two arms (87.1% versus 86.6%); however, a small but significant 5-year disease-free survival rate was detected in the SLNB group.⁹

The incidence of SLN metastases directly correlates with tumour thickness, ulceration and a variety of other known primary tumour factors (lymphatic invasion, mitotic rate, Clark level, anatomic site and patient age). Substantial agreement exists for considering SLNB the standard of care in patients with cutaneous melanoma > 1 mm in thickness.¹⁰ For thin melanomas (< 0.99 mm), the risk of lymph node metastasis is estimated to be approximately 5.1% only. Among this group, however, a risk of positive SLN up to 20% has been reported in melanomas with a thickness of 0.76–0.99 mm, associated with ulceration and/or mitotic index $> 1/\text{mm}^2$. In these patients, SLNB is therefore highly recommended. For melanoma ≤ 0.75 mm thick or less in presence of ulceration and/or mitotic index $> 1/\text{mm}^2$ and other established risk factors, the probability of detecting a positive SLN are less but not irrelevant and the indication for a SLNB should be discussed with the patient.

SLNB is a surgical procedure that involves preoperative lymphoscintigraphy, obtained through the injection of a radio-pharmaceutical (human albumin nanocolloid labelled with technetium ^{99m}Tc). The injection is intradermal, around the scar of the removed melanoma or close to the tumour if still present, and followed by early and late scintigraphic scans in the likely locations of lymphatic drainage. Once the location of the sentinel node(s) has been identified, cutaneous projection area of each single node is marked on the skin. SLNB is performed in the operating room, usually under local anaesthesia associated with sedation or under general anaesthesia according to the site of lymphatic basin. Prior to sterile preparation of the patient, the primary site is further injected intradermally with 0.5–1 mL of a vital dye (Patent Blue), to increase the sensitivity of the method and to facilitate the finding of the lymph node. The use of the vital dye for SLNB should be avoided if the primary tumour is located on the face because of the risk of permanent tattooing, and in the case of a pregnant patient because of the low but not rare risk of reported allergic reactions (about 1% of cases). If SLN is identified in the parotid or in a deep location, SLNB should be extensively discussed with the patient before surgery, because in these areas SLNB may require more extensive surgery and the patient is at a higher risk for potential complications.

The SLNB technique is very simple. Through a small skin incision, which takes into consideration the incision necessary for a subsequent radical lymphadenectomy, the district is entered and under the guidance of a radioisotope probe, tracing the blue lymphatic channels, the SLN(s) is identified and removed. Care should be taken to not disrupt or cauterize the lymph node capsule. Each SLN removed is checked *ex vivo* for radioactivity and the nodal basin is rescanned. In case of potential background or shine radiation from the primary melanoma sites, concomitant wide excision can be performed beforehand to decrease radioactivity disturbance. All lymph nodes that are coloured or that measure >10% of the radioactivity of the *ex vivo* count in the more radio-emitting sentinel should be considered sentinel nodes. Drains are infrequently required and most patients are discharged on the same day. The incidence of complications is low, mainly related to wound dehiscence/infection or lymphatic collection (seroma). The success of the procedure, which is related to a well-known learning curve, also depends on the location of melanoma and on the lymph node basin involved (95% in the axillary and inguinal regions and 85% in head and neck).

Histological examination of the SLN should be performed on thick sections cut from paraffin-embedded tissue. Intraoperative pathology evaluation is not recommended, because in frozen sections identification of single or small clusters of melanoma cells is more difficult and a potential loss of diagnostic tissue can occur during specimen sectioning. The histopathological analysis of the SLN needs multiple sections stained with haematoxylin–eosin for immunohistochemistry. Some standardized protocols define the number of histological sections, the interval between these and the type of immunohistochemical markers to use for histological examination of the SLN in melanoma, such

as those proposed by the European Organisation for Research and Treatment of Cancer (EORTC) Melanoma Group. The percentages of positive sentinel nodes are affected by the type of protocol used, with a range between 18 and 33%. Because of prognostic relevance, the histologic report should specify the number of SLNs analysed, the number of positive lymph nodes, as well as the characteristics of the lymph node metastasis, reporting the maximum diameter, site (subcapsular, parenchymal or mixed), parenchymal invasion and extracapsular extension. The presence of naevus cell clusters should be noted. In fact, the SLN is considered positive in presence of isolated tumour cells only, even if these are displayed with immunohistochemical techniques only.

Histological status of the SLN is the most powerful independent predictor of survival in clinically node-negative melanoma patients. A negative SLNB is associated with a 5-year melanoma-specific survival rate of approximately 92%. Recurrence and death may occur in this group of patients due to a false negative SLNB or a pure haematogenous pattern of metastases. A false negative SLNB occurs in up to 10% of patients and is defined as the rate of development of clinical nodal disease in the same nodal basin. The reasons for a false negative event after SLNB probably have a multifactorial origins, related to an incorrect identification of the SLN during the procedure, to the presence of in-transit microscopic disease and, finally, to the presence of a very small burden of disease undetected at histological examination.

Lymphadenectomy

Lymph nodes are the most frequent site of metastases of melanoma. The lymphatic basin (or basins) at risk depend on the location of the primary; for melanomas of the head and neck, the laterocervical lymph nodes; for those of the trunk positioned above the Sappey line (extending from the navel to the iliac crest to the second vertebra lumbar), the axillary lymph nodes; and for those of the trunk below this line and the lower limb, the inguinal lymph nodes. Even the epitrochlear and popliteal lymph nodes, although rarely, may be the site of locoregional metastases. The main purpose of lymphadenectomy is to provide a locoregional control of disease and it is indicated for patients with histo- and/or cytologically proven lymph node metastasis.

Lymph node involvement is diagnosed in different ways, most frequently after SLNB, but a quota of patients may present clinical evident metastases at diagnosis or during follow-up. In case of positive SLNB, 15–20% of patients subjected to lymphadenectomy present additional lymph node metastases in the dissected basin, confirming the value of surgery for regional control of disease. However, the role of completion lymphadenectomy after SLNB remains controversial.⁹ In an MSLT-I subgroup analysis of patients with nodal metastasis, a significant difference in 5-year overall survival was detected in patients who underwent completion lymphadenectomy versus those

who developed clinically evident nodal disease requiring delayed lymph node dissection. Moreover, less positive lymph nodes were present in the SLNB arm who underwent completion lymphadenectomy compared with those analysed after delayed lymphadenectomy in the observation group (1.4 positive nodes versus 3.3 positive nodes, $p < 0.001$).

Despite these results, the impact of radical lymphadenectomy after SLNB on prognosis still remains unknown, and the enrolment of patients with positive sentinel lymph node biopsy in the two ongoing prospective studies (MSLT-2 and MINITUB), investigating the role of completion radical lymphadenectomy after the SLNB positivity, is highly recommended. While waiting for the results of these studies, radical lymphadenectomy remains the standard of care in patients with lymph node metastases.

The general principle in performing lymphadenectomy for melanoma is the *en bloc* excision of lymph nodes with surrounding fat tissue. Every attempt should be made to minimize morbidity through preservation of the motor nerves and muscle. The relative frequency of complications after lymphadenectomy has led some groups to consider more limited interventions, particularly in patients with positive SLNs in locations at risk of more significant complications. Axillary radical lymphadenectomy should include complete dissection of level I, II and III lymph nodes, removing all fibro-fatty tissue around the axillary vein. A section of the pectoralis minor muscle is suggested by some for better access to level II–III lymph nodes or in presence of bulky level II and III nodes. During dissection, long thoracic and thoracodorsal nerves should be identified and sectioned only if directly involved by the tumour.

In the case of metastasis to the inguinal lymph nodes, the standard approach involves the removal of the inguinal, external iliac and obturator lymph nodes.¹¹ In the classic description of inguinal dissection, a longitudinal skin incision is employed, extending 2–3 cm supero-medial to the superior anterior iliac spine up to the apex of the femoral triangle. The skin flaps are created medially up to the pubic tubercle, the anterior margin of the gracilis and abductor muscles and laterally up to the superior anterior iliac spine and Sartorius muscle. The dissection continues deeply, through the incision of the fascia lata, over the underlining muscles and femoral vessels. The saphenous vein is sectioned at the apex of the femoral triangle and at the level of the saphenofemoral junction. Deep dissection (iliac and obturator) involves sectioning of the oblique muscles and the inguinal ligament and through an extra-peritoneal approach, access to the pelvic area of the iliac and obturator lymph nodes is achieved. Even if the use of inguinal lymphadenectomy is performed by some surgeons in selected cases (negative pelvic CT scan, negative lymph node of Cloquet, number of positive inguinal lymph nodes are ≤ 2 , absence of a lymphatic drainage deep the pelvis view lymphoscintigraphy), evidence is too low to recommend this approach and a proper designed trial on this topic is desirable.

For cervical lymph node metastasis, clear indications on the thoroughness of dissection are lacking and all the recommenda-

tions are supported by a low level of evidence and follow opinions of experts in this field. In case of clinically evident cervical lymph node metastasis, surgery is aimed at the removal of all five levels of lymph nodes (submandibular, jugular and supra-clavicular). In case of metastasis discovered after sentinel lymph node biopsy, selective lymphadenectomy, involving the removal of lymph nodes at different levels, depending on the site of the primary tumour, the site of the sentinel node and the lymphatic drainage highlighted at lymphoscintigraphy, is suggested. Removal of the superficial part of the parotid is recommended only if clinically involved, because of the high risk of nerve damage observed.

All lymphadenectomies are characterized by significant morbidity, which is variable depending on the site of dissection. Inguinal–iliac–obturator lymphadenectomy is the intervention burdened by the greatest number of complications by far (wound infection/dehiscence, lymphocele, lymphoedema and nerve damage) with an incidence that can reach up to 80%.¹² Aimed at reducing postoperative morbidity after inguinal lymphadenectomy, several variations have been proposed which consider skin-sparing techniques, sartorius muscle transposition and saphenous vein preservation. The benefits of these technical variants still remain uncertain, as no randomized trials have reported a clear reduction in postoperative morbidity. An interesting advancement to minimize surgical morbidity after inguinal dissection is videoendoscopic inguinal lymphadenectomy¹³ (Figure 9.1). After blunt dissection under the fascia of Camper, the working space is obtained using high-pressure CO₂ levels and three trocars are placed at a variable distance from the apex of the femoral triangle. The postoperative morbidity appears lower with respect to the open procedure, mainly for wound/skin-related complications, and the number of lymph nodes harvested seems comparable to that of conventional groin dissection. Nevertheless, before this technique is considered suitable for clinical practice, comparable oncological outcomes, lower postoperative morbidity and better quality of life should be assessed in an appropriately designed randomized controlled trial.

In patients who undergo lymphadenectomy, the number of positive lymph nodes plays an important prognostic value. If only one lymph node is metastatic, the 10-year survival rate is about 50%, dropping to 30% if 2–3 positive lymph nodes are found.¹⁴ The 'N'-ratio (i.e. the ratio between the number of positive lymph nodes and total lymph nodes removed) seems to have a completely independent prognostic impact. Patients with a low N-ratio (less than 0.1 or including between 0.11 and 0.25) have a significantly better prognosis than patients with a high N-ratio (>0.25).¹⁵

For the prognostic importance of the number of lymph nodes and the N-ratio, the extension and quality of surgery becomes a primary factor in a patient's prognosis. Despite this evidence, shared parameters about quality control of lymph node dissections for melanoma are still lacking. The recommendations of the National Comprehensive Cancer Network (NCCN) require

Figure 9.1 Videoscopic groin dissection for groin metastases. (a) Trocar positions; (b) Intraoperative view.

only a clear description of the anatomical limits of the dissection. The number of lymph nodes (with different limit values) and the *N*-ratio could be a simple and objective parameters of quality, but no consensus on their use in clinical practice has been found.¹⁶

Adjuvant therapy

Patients with lymph node metastasis are at high risk of recurrence and/or systemic metastases. For this reason, adjuvant (i.e. postoperative) therapy has been proposed to reduce the risk of death and recurrence in patients with high-risk melanomas. The only compound that has shown some positive therapeutic effects is interferon alpha.¹⁷ Several randomized studies, confirmed by a meta-analysis, showed a 13% reduction in the 5-year recurrence rate and an 11% reduction on the risk of death in patients treated with interferon. Although further studies are required to select patients who are most likely to benefit from this treatment, data on interferon treatment represent today the best referral values in investigating new therapeutic agents for adjuvant treatment. Adjuvant chemotherapy and immunotherapy with immunostimulatory agents (bacille Calmette Guérin/BCG), cytokines (interferon gamma, interleukin 2) and melanoma-specific vaccines have not demonstrated any therapeutic advantage. Among

vaccines, the Mage 3A vaccination seems the most promising but the results of the trial concluded in 2011 are still awaited. The exciting survival benefits seen in patients with metastatic melanoma treated with immune-targeted and target drugs (Ipilimumab and BRAF inhibitors) have suggested its use in the adjuvant setting but their potential benefit is still under investigation.

The use of adjuvant radiotherapy after lymphadenectomy for melanoma remains controversial and no significant improvement of the overall survival has been observed. For patients at high risk for regional relapse (multiple affected lymph nodes or extracapsular spread), adjuvant radiotherapy after lymph node dissection seems to improve local control and should be considered in this group of patients.¹⁸

Locoregional treatment

'In-transit metastases' or 'satellites' are defined as the locoregional spread in the lymphatic system between the site of the primary lesion and the main regional lymphatic basin. More than 20% of all recurrences for melanoma are in the form of in-transit metastases or satellites. The 5-year survival rate of these patients stands at 25–30%, with a better prognosis than other metastatic sites.

Figure 9.2 Hyperthermic isolated limb perfusion (HILP) for bulky metastatic melanoma of the leg. (a) Before and (b) response after treatment.

In the presence of cutaneous and subcutaneous metastases, the therapeutic choices depend on the number, size and location of the lesions. For a single or very few lesions, especially if the primary melanoma is associated with favourable prognostic factors, a simple radical excision represents the first-line treatment, possibly associated with SLNB, since the occurrence of occult metastases in regional lymph nodes is significant. Excluding these more favourable cases, the vast majority of patients present with multifocal and progressive lesions or bulky disease. In these cases, locoregional treatment should be proposed in absence of systemic metastases. For in-transit lesions located in the limbs, hyperthermic isolated limb perfusion (HILP) represents the gold standard of treatment¹⁹ (Figure 9.2). The rationale of HILP is the administration of a high dose of one or more chemotherapeutic drugs to the limb while avoiding systemic toxicity. During HILP, the femoral/axillary vessels are cannulated and the perfusion circuit is obtained through a specifically designed perfusion machine, which maintains an adequate blood flow under moderately hyperthermic conditions (39–41°C). Melphalan is the drug of choice, with a complete response in around 50% of cases and a 5-year survival rate of 28.5%. In cases of no response, relapse or in the presence of a high tumour burden, the association of melphalan with tumour necrosis factor alpha (TNF- α) provides a significant improvement in the complete response rate without an increase in toxicity. In patients with recurrence after HILP unfit for surgery, isolated limb infusion (ILI) can be used.²⁰ With respect to HILP, isolated limb perfusion is performed in absence of hyperthermia under hypoxic conditions (without oxygenation

of the perfusate) and is considered less invasive since the catheters are placed percutaneously. The combination of melphalan and actinomycin-D achieves a complete response rate in 38% and a partial response rate in 46% of cases, with a 5-year survival rate similar to that for HILP.

Recent evidence has suggested electrochemotherapy as a new therapeutic modality for patients with in-transit metastases from melanoma (Figure 9.3). Electrochemotherapy is based on the physical and biological principle of electroporation (i.e. the ability of an external electric field applied on biological tissues to increase, by using a short and intense pulse, the permeability of cell membranes to various molecules). The use of electrochemotherapy in the presence of cutaneous and subcutaneous metastases has proved effective and the technique has recently been standardized. The European Standard Operating Procedures of Electrochemiotherapy (ESOPE) classified the use of electrochemotherapy according to the type of tumour, the drug used (bleomycin or cisplatin), the route of administration (venous or intratumoural) and the type of electrode used.²¹ The main advantage is that electrochemotherapy is a minimally invasive procedure well accepted by patients. It is performed in a day hospital setting under local anaesthesia and/or sedation, with limited side effects and very few contraindications.

Electrochemotherapy has the considerable advantage, with respect to HILP and ILI, that it is easily repeatable in different sessions and can be applied to any region of the body. The complete response rate after a single session ranges from 9% to 100%, while the objective response varies from 62% to 100%, results that tend to increase after multiple sessions. Main prognostic factors identified as related to the tumour response are the nodule size and number.

In conclusion, in the presence of in-transit metastases, HILP remains the treatment of choice, as it ensures the highest rate of complete response, which is a factor that is able to influence both locoregional control and survival. ILI is a viable alternative, especially in frail patients with multiple comorbidities, for sites of disease distal to the middle third of the thigh. Electrochemotherapy is a promising technique that can be used in case of failure of HILP and isolated limb perfusion, as complementary treatment in combination with other locoregional therapies, or as an alternative where these are contraindicated or cannot be accomplished (metastases in the trunk, neck and head).

Distant metastases

The most common sites of metastases from cutaneous melanoma are extraregional lymph nodes, the lung, the brain, the skin and the liver, less frequently, bone, adrenal glands and gastrointestinal tract. In the presence of distant metastases, surgical treatment may have a dual purpose – palliative or curative. In the first case, surgery is mainly directed to treat a symptom that

Figure 9.3 Electrochemotherapy treatment for superficial metastases. (a) Hexagonal-array needle electrode for tumour electroporation; (b) cutaneous metastatic melanoma, baseline; (c) follow-up at 44 weeks; (d) Follow-up at 60 weeks.

adversely affects the quality of life of a patient. For example, in selected patients with metastases to the gastrointestinal tract, surgery may offer good palliation for bleeding or intestinal occlusion. On the other hand, radical resection should be considered as first-line therapy whenever complete removal of all disease can be accomplished, since surgery with curative intent ensures 5-year survival of up to 30%, a result not obtainable with other systemic therapies.²² For this reason, radical surgery should be considered in selected patients after multidisciplinary discussion, taking into consideration, as prognostic factors, the metastatic site (skin versus lung versus other sites), the number of metastases, the number of organs involved, the disease-free interval, the doubling time of the lesions, the LDH levels and the performance status of the patient.

However, for the majority of patients with stage IV disease, radical surgery remains contraindicated for the presence of

unresectable, progressive or disseminated disease.²² These patients should be considered for systemic therapy or palliative care. Until a few years ago, patients with metastatic melanoma had few treatment options. They had been treated with dacarbazine or other palliative chemotherapies, with poor results (median survival 6.2 months and only 25.5% of 1-year survival). Over the last decade, significant progress in understanding the molecular pathway of tumourigenesis and metastasis of melanomas, together with the definition of the regulatory role of the immune system in these mechanisms, led to the discovery of new drugs that have shown an encouraging clinical activity against metastatic melanoma. Among these, ipilimumab is a monoclonal antibody that blocks the cytotoxic T-lymphocyte-associated antigen (CTLA-4), a molecule that has an inhibitory role in T cell activation. Treatment with ipilimumab promotes antitumour immunity against

melanoma, showing significant improvement in survival for patients with metastatic disease, with a reported median survival of 10 months.²³ Another recent finding, closely linked to molecular biology of melanoma cells, was the discovery of the role of protein kinase pathway in tumour progression, which is regulated by the protein BRAF. Mutations in BRAF protein (mainly at codon 600) are found in half of patients with melanoma, resulting in constitutive activation of the kinase pathway. Almost 90% of BRAF mutations are in the codon V600E, which is specifically inhibited by the monoclonal antibody vemurafenib. In the clinical setting, vemurafenib has been shown to improve tumour response rate and overall survival.²⁴ Despite the continuous improvement in target therapy for metastatic melanoma and new promising drugs under study, the response rate for ipilimumab is low and the durability of clinical response of vemurafenib remains poor. For these reasons, further trials evaluating combination therapies are essential to improve the results of treatment of stage IV melanoma in the near future.

Non-cutaneous melanomas

After cutaneous melanoma, ocular melanoma represents the second most common type and the most common primary intraocular malignant tumour in adults. The vast majority of ocular melanomas originate from uvea, whereas conjunctival melanomas are far less frequent. Incidence of uveal melanoma has remained stable over the last three decades. Patients with uveal melanoma are often asymptomatic and the tumour is diagnosed upon clinical examination with great accuracy. Fine needle biopsy is usually not suggested, as seeding of the needle tract has been reported. The choice of treatment takes into account many factors; among them, the size of the tumour is the most important. Historically, enucleation has been considered the definitive treatment of uveal melanoma, now restricted for large or symptomatic lesions. The alternative treatment most commonly adopted is radiotherapy. Among the radiotherapeutic strategies, the most common treatment is plaque brachytherapy, in which a small plaque with radioactive seeds is attached to the outside surface of the eye, overlying the tumour.²⁵ The plaque is left in place for a few days and then removed. After plaque radiotherapy, the survival results are the same as that after enucleation. Despite an optimal local control, half of patients develop metastases within 15 years after treatment of the primary tumour. The most common site of metastasis for uveal melanoma is the liver, which is also the first site of metastasis for 80–90% of ocular melanoma patients. Other common sites of metastasis include the lung, bones and the skin. The survival time after diagnosis of liver metastases depends on the extent of systemic spread. Recent findings in cytogenetics and genetics have allowed a better prognostic stratification and the determination of tumours with higher metastatic potential.²⁶ However, an effective systemic therapy is still lacking.

Primary mucosal melanomas arise from proliferation of melanocytes located in mucosal membranes of the gastrointestinal, respiratory and urogenital tract.²⁷ More than half of mucosal melanomas originate from the mucosa of the nasal and oral cavity and the accessory sinuses. Less frequently, the sites of origin of mucosal melanomas are ano-rectum, vulva and vagina. Mucosal melanomas can arise in almost any part of mucosal membranes, with a reported 1% of cases of occult disease. The lack of early and specific symptoms contributes to late diagnosis, and consequently to adverse prognosis. Because of their low incidence, no established protocols for treatment are available, and surgery represents the mainstay of therapy. More recently, more conservative surgery has been advocated, since a demolitive approach does not seem to show an advantage for survival. Adjuvant radiotherapy can provide better locoregional control in some locations, but did not show improvement in survival. Compared with cutaneous and ocular melanoma, mucosal melanomas have the lowest percent of 5-year survival. There is no effective systemic therapy for these aggressive tumours. Recent advances in molecular biology underlying mucosal melanomas have identified KIT as a potential marker for targeted therapy in around 25% of patients.²⁸ Clinical trials with KIT inhibitors are ongoing.

CHAPTER 10

Non-melanoma skin cancers

Michael Findlay^{1,2,3} and Mina S. Ally¹

¹Stanford University, Stanford, CA, USA

²Division of Cancer Surgery, The Peter MacCallum Cancer Center, East Melbourne, Australia

³The University of Melbourne Department of Surgery, Melbourne, Australia

We live in an age of increased awareness of the linkages between genetics, skin type, ultraviolet light exposure and the development of skin cancer. Among the general public, melanoma receives the bulk of attention in this area as a tumour (of melanocytes) that demonstrates early metastasis relative to its tumour burden. However, melanoma represents less than 2–5% of all cutaneous malignancies. The other 95–98% are the non-melanoma skin cancers and, as a group, these are the most common form of cancer in humans. The extensive incidence of the non-melanoma skin cancers (NMSC) within humans is often underrepresented in cancer rankings. NMSC is usually excluded from these rankings by mention in the fine print of cancer fact sheets. Recent estimates demonstrate that more cases of NMSC have occurred in the past 30 years than all other forms of cancer combined.¹

Basal cell carcinoma (BCC) and squamous cell carcinoma (SCC) are the most common forms and account for the vast majority of NMSCs. Despite growing public awareness campaigns on the harmful effects of ultraviolet (UV) exposure, the incidence of NMSC has been rising by 3–8% per year since 1960, with as much as 300% increase in the past two decades in countries such as the United States.² This trend is predicted to continue as populations age worldwide. Despite this increase, the death rate from NMSC is decreasing due to increased awareness, earlier diagnosis and improved treatment options. A thorough understanding of the NMSCs and current management options is essential to continue this important survival trend.

Basal cell carcinoma

Basal cell carcinoma is a malignant neoplasm of keratinocytes that is exceptionally common (>80% of skin cancers) and rarely metastatic. In the United States it affects 1 million people each year. BCCs may be either sporadic or related to heritable mutation(s). Most BCCs are sporadic, with environmental exposures being the major aetiological factors, with a latency period of anywhere between 20 and 50 years from exposure to

the development of BCCs. For this reason, most sporadic BCCs occur in older males (>50 years) with fair complexions (Fitzpatrick skin types 1 and 2) as this group has the greatest lifetime exposures to environmental influences.

Environmental influences

Intensive, intermittent UV exposure (particularly UVB rays) resulting in sunburn and blistering (especially during childhood/adolescence) is a major risk factor for BCC. Fair skin types (Fitzpatrick skin types 1 and 2) and individuals in hot sunny climates are at greater risk of incidental intermittent sunburn. In Australia, which experiences the greatest UV solar irradiation per area of any continent, these factors combine to produce the highest incidences of NMSCs and melanoma in the world. Additional environmental factors include tanning bed use, chronic inflammation (burns, scars), ionizing radiation, arsenic and hydrocarbon exposure. The association between human papillomavirus and BCC is not yet clear, however immunosuppression poses greater risk of BCC development, particularly among organ transplant recipients using photosensitizing antifungal prophylaxis such as voriconazole.

Genetic basis

Multiple types of genes have been implicated in the development of BCC, including tumour suppressor genes, DNA repair genes and genes involved in skin and skin appendage pigmentation. Approximately 90% of sporadic BCCs have activating mutations in the hedgehog signalling pathway, resulting in uncontrolled proliferation of epidermal basal cells. This pathway was identified by studying patients with basal cell naevus syndrome (BCNS or Gorlin syndrome), an autosomal dominant disease with constitutive mutations of the hedgehog pathway. The specific gene involved in the majority of cases is the tumour suppressor gene *PATCHED* (chromosome 9q), mutations of which lead to an increased risk of developing multiple BCCs from a young age, as well as a cluster of keratocystic odontogenic tumours (KCOTs; 75% of patients), palmar and plantar pits (Figure 10.1), multiple skeletal abnormalities (e.g. bifid

Figure 10.1 Palmar pits in Gorlin syndrome. The patient's mother and brother were also both affected, with greater penetrance of phenotypic changes, but all three have palmar pitting.

ribs, frontal bossing), and calcification of the falx cerebri. Approximately 10% of BCNS patients do not develop BCCs, indicating the involvement of multiple genes. The tumour suppressor gene P53 and melanocortin-1 receptor gene are also important for the development of BCC, but much less specific to this tumour. Those with pigment disorders and defects in DNA-repair mechanisms, such as albinism and xeroderma pigmentosum, respectively, are also more susceptible to NMSC development.

Clinical presentation and classification

BCCs usually present on sun-exposed areas, such as the head and neck, although they can occur at more photo-protected sites, particularly in the immunosuppressed. Due to its prevalence, many different classification schemes have been developed for BCC. A clinicopathologic classification is the most common in clinical use, but suffers from significant overlap between specific types (e.g. between desmoplastic/morpheaform and infiltrating) and multiple names used for the same or similar subtypes. Commonly described subtypes include: superficial, nodular, micronodular, morpheaform/desmoplastic, infiltrating, pigmented and mixed. A simpler, management-oriented approach is to classify BCCs as either discrete or diffuse, referring directly to how easy it is to judge their margins. This approach groups poorly circumscribed lesions (e.g. micronodular, morpheaform, infiltrative) on the basis that wider margins of excision are necessary to achieve clearance when compared with discrete lesions (such as superficial and nodular types). The anatomic location of BCCs may also favour the development of a particular subtype.

Superficial basal cell carcinoma

Superficial BCCs (Figure 10.2a,b) typically appear on the trunk as single or multiple well-defined erythematous finely scaled patches or plaques with pearly edges. They can be confused with

actinic keratosis, superficial SCC or eczema. Any solitary patch of 'eczema' not responding to treatment should raise suspicion for superficial BCC. Numerous superficial BCCs have a well-known association with a history of arsenic exposure.

Nodular basal cell carcinoma

Nodular BCC (Figure 10.2c,d), the most common subtype (50–85% of tumours) typically presents as a pearly papule or nodule with raised, rolled edges and telangiectasia. These features are particularly obvious when the lesion is put under tension (to demonstrate pearly) and then released (to show refilling of telangiectasia). Ulceration may sometimes be present, hence the term 'rodent ulcer' and if left untreated local invasion can occur.

Micronodular basal cell carcinoma

Micronodular BCC (Figure 10.3a) appears as numerous very small tumour nests upon histopathology sectioning. The nodules do not appear to be contiguous with each other on individual sections, but sequential sections usually demonstrate that the individual nests are part of a complex network of intercommunicating tumour processes. The apparent lack of continuity between individual nests on single sections makes it difficult to comment on the adequacy of tumour clearance without a wide, uninvolved radial margin. This contributes to its higher recurrence rate when compared with superficial and nodular BCCs. It is considered to be of intermediate aggressiveness, with the other diffuse forms of BCC (e.g. morpheaform) demonstrating a worse prognosis again. Clinically, it can present as flat or elevated tumours that are most commonly found on the back.

Morpheaform or desmoplastic basal cell carcinoma

Morpheaform or desmoplastic BCCs (Figure 10.3b) appear as depressed, scar-like, ill-defined, indurated plaques often with focal penetration of tissues. Direct perineural invasion can occur, producing paraesthesia, hyperaesthesia or paralysis in the affected area, but due to the absence of haematogenous spread with these tumours, skip lesions are not found. These subtypes are associated with a worse prognosis and have an increased risk of recurrence following treatment.

Infiltrative basal cell carcinoma

Infiltrative BCC (Figure 10.3c) is similar to morpheaform/desmoplastic because clinically they are diffuse, can look like a skin reaction or scar and histologically, they demonstrate nests and cords of tumour invading the surrounding tissues. Unlike morpheaform BCCs, there is minimal to absent desmoplastic stromal response (the surrounding tissues can look relatively bland).

Pigmented basal cell carcinoma

Pigmented BCCs (Figure 10.3d,e) present as pigmented variants of the other subtypes, including flat patches, plaques, papules or nodules and are often difficult to differentiate from seborrhoeic

Figure 10.2 (a) Superficial BCC near the right inner canthus. (b) Representative histopathology specimen for superficial BCC – small islets of basaloid tumour cells with peripheral palisading. Nests are well circumscribed and have effaced the dermo-epidermal junction without invading the papillary dermis. (c) An ulcerated nodular BCC on the nose, demonstrating classic pearly and telangiectasia around an area of central ulceration. (d) Representative histopathology specimen for nodular BCC demonstrating islands of basaloid cells with peripheral palisading and peri-nest clefting from the surrounding specialized stroma (an artefact of processing). Note the relative basophilia of the tumour compared to the surrounding stroma.

keratosis and malignant melanoma. Pigmented lesions presenting in the normal anatomical distribution of BCC are more likely to be BCC than melanoma, but both should always be entertained in the differential diagnosis of pigmented lesions.

Mixed basal cell carcinoma

It is common to see patterns of superficial BCC mixed with micronodular or other variants. The margin of excision should be determined based on the required margin for each part and its proximity to the radial and deep margins.

Basisquamous cell carcinoma

The basisquamous cell carcinoma is an uncommon and unusual tumour that shares features of both BCC and SCC. Sometimes they are alternatively reported as a basaloid tumour with squamous features. They are to be distinguished from BCC by

their potential for malignancy and therefore clinically, should be managed as though they are an SCC.

Diagnosis

Dermoscopy

Dermoscopy aids with evaluation of pigmented cutaneous lesions and can be used to help differentiate pigmented BCC from melanoma. Typical findings of BCC on dermoscopy include the absence of a pigment network and at least one of the following: ulceration, multiple blue-grey globules, leaf-like areas, arborizing vessels, large blue-grey ovoid nests and spoke wheel areas.

Biopsy

Definitive diagnosis is made on histology following a punch, shave or excisional biopsy of the lesion. Histology of superficial BCC (Figure 10.2b) usually reveals a basophilic tumour (blue)

Figure 10.3 Representative histopathology specimens. (a) Micronodular BCC – uniformly small nests of neoplastic basal cells with rounded peripheral contours extending widely throughout the dermis with surrounding specialized stroma. (b) Morpheaform BCC – strands of basaloid tumour cells extending deeply into the dermis embedded with a dense fibrous stroma. (c) Infiltrative BCC – long, thin strands of basaloid tumour cells penetrate deeply among the collagen fascicles. (d) A 4 mm pigmented BCC in the central field could easily be diagnosed as a melanoma. An incidental superficial BCC is seen in the lower left corner. (e) Pigmented BCC – numerous melanocytes are present among the basaloid tumour nests and there are occasional melanophages within the stroma.

on standard haematoxylin and eosin (H&E) staining. Buds of basaloid cells extend from the epidermal basal layer into the reticular dermis. Nodular BCCs (Figure 10.2d) have nests of large basaloid cells with peripheral palisading in the papillary or reticular dermis. They may demonstrate peri-nest clefting consistent with retraction from surrounding stroma but this is usually a processing artefact. Micronodular BCC (Figure 10.3a) is composed of multiple microscopic nodules smaller than 15 μm , making it difficult to interpret tumour clearance when there are close margins. Tumours become infiltrative (Figure 10.3c) when basaloid islands lose their epidermal connections and invade the underlying dermis, often as sheets or finger-like projections of tumour cells without much stromal reaction. In contrast, morpheaform BCC (Figure 10.3b) consists of strands of tumour cells extending deeply into the dermis, embedded within a dense fibrous stroma. Pigmented BCCs (Figure 10.3e) have similar histology to the nodular subtype with numerous melanocytes among the tumour nests and melanophages in the stroma.

Staging for basal cell carcinoma

BCC and SCC share a common staging system. This is presented later in this chapter (see Squamous cell carcinoma).

Course and prognosis

BCCs grow slowly (doubling time 6–12 months) and the majority present at stage 0 or 1. Individuals presenting with one BCC are at increased risk of having more lesions at the time of diagnosis and a 3-year cumulative risk for a second primary of 44% (10-fold increase over the general population).³ They can be locally invasive, involving subcutaneous tissue, muscle and bone (Figures 10.4 and 10.5). Micronodular, morpheaform or infiltrative BCCs are more likely to recur after treatment. Long-term follow-up and annual skin examinations are warranted in those with a history of BCC, as they are also at an increased risk of developing other skin cancers. BCCs exhibit stromal dependence where tumour cells cannot engraft elsewhere without being transplanted along with adjacent stromal cells. Correspondingly, the incidence of metastasis is reported to be less than 0.55% and is associated with larger primary tumour size, greater depth of invasion, previous irradiation and central facial position rather than tumour subtype. When metastasis occurs, lymph nodes and lungs are the most commonly involved. Since 1981, 238 cases of metastatic BCC have been reported, most of which occurred in middle-aged men with an average tumour size of 7.5 cm and a median time of 9 years between primary tumour and first sign of metastasis.⁴ Once metastasis does occur, the median survival is 10 months.

Management

Complete surgical excision with pathology confirmation remains the gold standard in the management of BCC. Their abundance in clinical practice, slow doubling time, stromal dependence and significant rates of spontaneous regression (most studies demonstrate at least some degree of regression in

Figure 10.4 Local invasiveness of BCC of the left temple. Marked central tumour necrosis, chronic discharge, ipsilateral brow ptosis and loss of forehead wrinkling consistent with locally advanced BCC destroying the frontal branch of the facial nerve and underlying temporal bone. The tumour had reached the anterior cranial fossa.

around 20% of lesions⁵) have prompted the development of numerous treatment options, each with their relative merits. However, their potential to display a mixed clinicopathologic picture, variability in aggressiveness based on type, site and patient factors and the fact that recurrent BCCs tend to demonstrate poorer prognosis, should prompt management based on the most effective modality in the individual to achieve complete removal or destruction of the tumour. As a result, treatment varies depending on anatomic location, BCC subtype, tumour size, depth of invasion and patient comorbidities (Table 10.1).

Non-operative management

Topical therapies

Topical therapies provide a minimally invasive approach to manage BCC in specific situations. The success of the therapy is determined by the ability of the topical agent to reach the entire tumour, the tumour response and the compliance of the patient.

Cryotherapy uses liquid nitrogen to destroy superficial BCCs. It requires a minimum of two freeze–thaw cycles achieving temperatures of -50°C to destroy the tumour with treatment of a margin of normal tissue to ensure destruction of subclinical

Figure 10.5 High-risk zone for basal cell carcinoma.

Table 10.1 Treatment options for basal cell carcinoma

Treatment modality	Best indication
Topical	
Cryotherapy	Small superficial BCC
Imiquimod ^a	Biopsy confirmed non-facial superficial BCCs <2 cm
5-Fluorouracil ^a	Non-facial superficial BCCs <2 cm
Oral	
Vismodegib	Locally advanced and metastatic BCC; neoadjuvant use prior to surgery to reduce surgical defect size of all subtypes
Photodynamic therapy	Multiple superficial or thin nodular BCCs
Radiotherapy	Primary BCCs in those unwilling or unable to undergo surgery; adjuvant therapy post surgery for remaining positive margins
Procedural	
Standard excision	Workhorse – surgical management of BCC, useful for all tumour types in all areas but clearest benefits in non-aggressive primary BCCs in non-high-risk locations
MMS ('Gold standard')	Selective application – primary facial morpheaform or infiltrative BCC; recurrent BCC; any BCC in a high-risk location
Electrodesiccation and curettage	Non-aggressive primary BCCs <3 cm in low-risk locations; unable or unwilling to tolerate surgery
Pulsed dye laser ^b	Superficial and nodular BCCs <1.5 cm

^a Can be tried for the off-label use of small nodular BCC.

^b Long-term follow-up outcomes still awaited.

extension. This method lacks histologic tumour confirmation but cure rates are reported to be over 95%. Care must be taken when treating BCCs near the eye. Adverse outcomes include scarring, hypo- or hyperpigmentation and the possibility of obscuring tumour recurrence by scar tissue. Some have reported greater patient satisfaction with surgical excision compared to cryotherapy due to better cosmesis.

Imiquimod 5% cream is an immune response modifier that increases the T-helper response by inducing interferon- α , tumour

necrosis factor- α and cytokines to destroy dysplastic keratinocytes by acting on toll-like receptor 7 (TLR7). Although it is only US Food and Drug Administration (FDA)-approved for biopsy confirmed non-facial superficial BCCs <2 cm in size, some have shown efficacy in the treatment of nodular BCCs. However, care should be taken with off-label treatment due to reports of recurrences with increased subclinical extension due to selective clearing of superficial tumour. Furthermore, there is significant genetic variation in toll-like receptors between individuals, with

some individuals being unable to respond to imiquimod therapy as a result. Adverse reactions include local skin irritation (the severity may or may not correlate with histological clearance) and hence it should not be applied near the eye.

5-Fluorouracil has also been used for superficial and nodular BCCs. A systematic review found clearance rates of up to 90% for superficial BCCs. However, adverse reactions of erythema, pruritus and pain limit its use. Imiquimod and 5-fluorouracil treatment should be restricted to small tumours in low-risk locations in patients who will not or cannot undergo treatment with more-established therapies of known long-term clearance rates.⁶

Oral therapy

The FDA-approved oral hedgehog pathway inhibitor vismodegib has shown efficacy in the treatment of locally advanced and metastatic BCCs,⁷ in reducing the size of existing BCCs and development of new BCCs in those with BCNS.⁸ A recent pilot study also demonstrated its potential to reduce tumour size prior to surgery for BCCs of all histologic subtypes. However, histologic changes to the tumour with this drug may cause difficulty in determining clear margins during Mohs surgery. In addition, the optimal duration of neoadjuvant treatment has not yet been determined. Adverse effects are the main limiting factor to continued use of vismodegib, including muscle cramps, hair loss, dysgeusia, weight loss and fatigue. With drug discontinuation the adverse events resolve but tumour regrowth occurs within months. Prolonged use may result in secondary acquired resistance.

Photodynamic therapy

Photodynamic therapy (PDT) involves the topical application of a photosensitizing agent on the desired treatment area, with subsequent activation of the drug by visible light to create reactive oxygen species to destroy neoplastic cells. Topical δ -aminolevulinic acid or methylaminolevulinate produce the photosensitizer protoporphyrin IX semi-selectively within tumour cells. In 2005, an international consensus on the use of PDT for NMSC recommended it as first-line treatment for superficial BCC. It is less effective in nodular BCC subtypes due to the thickness of the tumour limiting absorption of the topical medication into the dermis.⁹ Although studies have demonstrated superior cosmetic outcomes of PDT compared to surgical excision, some tumours do not respond to treatment and it is associated with higher recurrence rates than surgery with long-term cure rates for superficial BCC of approximately 75%. Adverse reactions include erythema and pain. The inconvenience of multiple hospital visits makes it unsuitable for some patients. PDT should generally be reserved for those with tumours not amenable to other established treatment methods or for those with multiple BCCs, such as BCNS patients.

Radiotherapy

Radiation therapy can be used for primary BCCs in those unwilling or unable to undergo surgery or as an adjuvant therapy post surgery for remaining positive margins. Control

rates of over 90% have been reported, although there may be potential for aggressive recurrences post treatment. Disadvantages include lack of histologic verification of tumour removal, prolonged treatment course and poor cosmetic outcomes. Radiotherapy is contraindicated in patients with BCNS or xeroderma pigmentosum (XP), as ionizing radiation can induce development of new BCCs within the radiation field.

Operative management

Current controversies in surgical management of BCC

Significant debate remains as to what is the most appropriate definitive treatment modality for BCC, especially whether standard surgical excision or Mohs micrographic surgery (MMS) is the most appropriate definitive surgical treatment. The two modalities use different processing techniques to determine margins, which can make direct comparison difficult. Compounding this in the literature is the variable use of clinical versus pathological margins, lack of direct comparison between these modalities in clinical trials and a paucity of appropriate outcome measures and suitable long-term follow-up. One example is the use of incomplete excision to suggest MMS provides better outcomes. Incomplete excision is an uncommon outcome following standard surgical excision using an appropriate margin. In specific instances, further resection may be stopped and the defect dressed or skin grafted for later reconstruction (delayed reconstruction after pathology evaluation; DRAPE¹⁰) if the formal histopathology result is clear. This minimizes the loss of important anatomical structures and has been referred to by some as 'slow Mohs'. If incomplete, further resection is undertaken, but the initial resection is considered as incomplete. MMS provides the benefit of being able to undertake multiple cycles of resection and microscopic evaluation on the same day, but the number of cycles is not generally included in statistics for comparison. Although DRAPE may be inconvenient for the patient, this approach provides excellent, cost-effective clearance while preserving important structures to aid the post-operative outcome. Therefore studies comparing modalities should be interpreted carefully as they often lack comparable definitions, intentions, terms or techniques that permit appropriate direct comparison. We will present each of these techniques and discuss their relevant merits and drawbacks in an effort to provide a balanced assessment.

Standard surgical excision

Surgical excision for BCC produces cure rates in excess of 90%. A meta-analysis (89 studies and 16 000 lesions) identified that a 3 mm clinical margin for non-morpheaform BCC resulted in a cure rate of over 95% for lesions under 2 cm in diameter. Incomplete excision in this study was associated with a 27% recurrence rate. Although this is somewhat high, incompletely excised lesions often do not show any additional tumour on re-excision and such re-excision usually results in cure in this rarely metastatic tumour. Standard surgical excision is one of the most widely used and reliable approaches to achieve definitive tumour

excision with confirmatory histopathology in a relatively cost-effective manner. However, incomplete excision rates for aggressive subtype primary BCCs or recurrent BCCs have been shown to be higher with this method compared to MMS, with over 10% incomplete excision rates in some reported studies. Although this may reflect the clinical practice of staged excision/DRAPE, proponents of Mohs correctly identify the capacity of Mohs to produce equivalent or higher cure rates in a single visit. A wider radial margin (5 mm) is typically used for diffuse lesions up to 2 cm in diameter for this reason. This wider margin may increase the defect size relative to MMS with potential significance for aesthetically or functionally sensitive areas such as in the central face. Reconstruction of these areas is commonly undertaken as aesthetic units for improved postoperative appearance, with MMS demonstrating benefit if the excision can be contained within a specific subunit. Standard surgical excision remains the workhorse for definitive BCC excision and is one of the most cost-effective means to manage the millions of BCCs that occur worldwide every year.

Mohs micrographic surgery

MMS is considered by many as the gold standard in BCC removal by providing equal or higher rates of tumour clearance when compared with other modalities. MMS involves histological analysis of tissue margins and therefore provides tumour clearance with maximal tissue conservation in areas of high risk for recurrence (periorbital, periauricular and central face), resulting in smaller surgical defects compared to standard surgical excision (Figure 10.5). Five-year recurrence rates for primary and recurrent BCCs treated by MMS are approximately 1–2% and 4–7%, respectively. Therefore it is especially useful for primary facial BCCs with aggressive clinicopathologic subtypes (morpheaform or infiltrative), recurrent facial BCCs and any BCC in a high-risk location. The use of MMS to treat the majority of BCCs is probably inappropriate however. The process can be lengthy for the patient and the Mohs practitioner as a number of cycles of excision, processing and interpretation may be necessary to achieve clearance. From a health economics perspective, MMS is significantly more expensive than standard excision, and for non-recurrent disease it has not been shown to produce better 5-year outcomes.¹¹

For these practical reasons, MMS is applied selectively in centres that offer it as a treatment modality. It is likely that formalized criteria for its use will be required into the future as populations age, rates of NMSC increase and health budgets become tighter.

Electrodessication and curettage

Electrodessication and curettage is an efficacious and cost-effective treatment modality, however, it is operator-dependent. Its use should be limited to small (<3 cm) non-morpheaform primary BCCs in low–moderate risk locations. Larger (>2 cm) and more aggressive tumours are associated with lower clearance (84%), when compared with the excellent clearance rate (98%) achieved in tumours <1 cm.

Pulsed dye laser

Pulsed dye laser (PDL) 595 nm has shown some efficacy for superficial and nodular BCCs. It targets the vascular network of these tumours, leading to size reduction and complete regression in some cases. Clearance rates up to 90% with four treatments have been reported for small superficial and nodular BCCs (<1.5 cm). Cure rates were lower with larger tumours. The use of larger spot sizes and double stacked pulses may allow single treatments to clear BCCs¹² but only a limited number of studies have been performed and the long-term effectiveness is unclear. Adverse events include hypopigmentation and scarring.

Squamous cell carcinoma

SCC is the second most common type of skin cancer, with an estimated annual incidence of 250 000 cases in the United States. It is the second most common cancer in the White population.

SCC is a malignant neoplasm of suprabasal epidermal keratinocytes with full-thickness epidermal dysplasia. They may arise *de novo* or from precursor lesions (actinic keratosis; AK), which have partial-thickness epidermal dysplasia. AKs are not considered to be a premalignant lesion, but rather an important sign of UV-induced photo-damage that signals an increased risk of NMSC. Their estimated progression rate from AK to SCC is 0.025–16% per year. Bowen's disease is the eponymous name for SCC *in situ* (SCCIS) and once the dysplastic keratinocytes have invaded the basement membrane, it becomes an invasive SCC. Although less common than BCCs, SCCs carry a risk of metastasis and death. Despite the rising incidence of SCC, there is a 20% reduction in mortality due to increased public awareness and more aggressive treatment of highly invasive tumours.

Aetiology

Increasing age and chronic UV exposure, including tanning bed use, are the most significant risk factors for SCC development, with a sharp increase in incidence over the age of 40. Approximately 90% of SCCs and over 75% of AKs have inactivation of the tumour suppressor gene p53 secondary to UV damage. p53 usually induces apoptosis of UV-damaged cells, thus preventing the development of dysplastic keratinocytes. In patients who received long-term therapy with psoralen and ultraviolet A (PUVA) for psoriasis, there is a 30-fold increased risk of NMSC, particularly SCCs. Additional risk factors include male gender, low Fitzpatrick skin type, albinism, XP, epidermolysis bullosa, human papillomavirus (HPV) infection, smoking, previous ionizing radiotherapy treatment, chronic inflammation and irritation and chemical carcinogens, such as arsenic and aromatic hydrocarbons. Immunosuppressed individuals, particularly organ transplant patients or those with leukaemia and lymphoma, have a significantly increased risk of SCC, mainly in sun-exposed sites with tumours typically developing 3–7 years after the onset of chronic immunosuppression. A third of individuals with epidermodysplasia verruciformis

develop SCCs due to chronic HPV infection. When SCC develops in an area of chronic inflammation and scarring, it is termed a Marjolin's ulcer (Figure 10.6f). This diagnosis should be considered in any non-healing wound as it carries a 50% risk of metastasis.

Mutational profiling of cutaneous SCC has been evolving over the past decade in an effort to understand SCC biology and identify molecular targets for novel therapeutics. Mutations involving *RAS* are one of the more common types, including *HRAS* and *KRAS*, but others include *TP53*, *CDKN2A*, *PIK3CA*, *MYC*, *FGFR3* and *VHL*. Of note, the use of RAF inhibitors in melanoma patients has resulted in the development of cutaneous SCC with a strong association with *RAS* mutations and epidermal growth factor receptor (*EGFR*) mutations are present in over half of all aggressive SCC.¹³

Clinical presentation

SCCs typically arise in sun-exposed sites (e.g. head, neck, ears, dorsal hands, lips and legs). In those with higher Fitzpatrick skin types, they may arise on both sun-exposed and protected sites. SCCs usually present as a changing solitary lesion developing from a pre-existing AK or Bowen's disease. AKs (Figure 10.6a) appear as multiple ill-defined scaly erythematous macules, papules or plaques, ranging in size from 2 mm to >2 cm, whereas Bowen's disease (Figure 10.6a) is usually a well-defined solitary patch/plaque. Both of these precursor lesions can be confused with eczema or psoriasis, however they are typically asymptomatic and do not respond to topical steroids. The development of tenderness, increased size or scale and erosions may represent progression to SCC. In the setting of immunosuppression, multiple SCCs may develop in an eruptive fashion.

The most common appearance of an SCC is a firm, solitary, skin-colored or erythematous hyperkeratotic papule or plaque (Figures 10.6c,f). It may also present as a pigmented lesion, chronic ulcer, smooth nodule, cutaneous horn or even a verrucous lesion. As the tumour progresses it invades and can become fixed to the underlying structures. Examination of regional lymph nodes is essential to exclude lymph node metastasis presenting as a non-tender enlarged mass.

Genital and perianal SCC may develop in the setting of lichen sclerosus et atrophicus in both men and women. Similarly, chronic evolving warty lesions in the perineal area and red velvety plaques on the penis are alternative presentations of SCC.

Keratoacanthomas (KA) (Figure 10.6b) are rapidly growing nodules with a central keratotic crater that can increase to several centimetres across within a few weeks followed by gradual spontaneous resolution. They typically arise in the sun-exposed extremities of elderly individuals. Due to the potential for local destruction and aggressive behavior they are regarded as a clinical subtype of SCC but do not metastasize and have a self-limiting course. Complete surgical excision to permit microscopic visualization of the junction between normal skin and the edge of the lesion is necessary to rule out well to moderately differentiated SCC and therefore surgical excision is usually

warranted, particularly if the lesion has been present for some time at presentation.

Diagnosis

As with BCC, definitive diagnosis of SCC is made on histology following a punch, shave or excisional biopsy, but clinical presentation with a hyperkeratotic or ulcerated lesion in actinic skin is often highly suggestive of SCC over BCC. The biopsy should be of sufficient depth to differentiate between *in situ* and invasive disease. For keratoacanthoma an excisional biopsy is recommended as the diagnosis depends on the overall architecture of the tumour. The presence of solar elastosis and marginal keratinocyte atypia suggests that the SCC is derived from a prior actinic lesion, whereas scar tissue may represent recurrent disease or SCC development within a prior scar. Immunohistochemical panels incorporating the cytokeratins and CD44 are often used to establish the diagnosis when lesions are poorly differentiated.

Histology usually reveals a predominantly eosinophilic (pink) tumour on standard H&E sections, with a combination of normal and atypical squamous cells arranged as single cells, nests of cells or a single mass. Full-thickness involvement of the epidermis indicates *in situ* disease (Figure 10.7a), whereas dermal involvement represents invasive SCC (Figure 10.7b). Subcutaneous involvement is unusual. Well-differentiated tumours retain squamous features such as foci of keratinization in concentric rings of squamous cells, known as 'keratin pearls'. Keratin production is reduced with loss of differentiation. The risk of recurrence and metastasis is 28.6% and 32.8%, respectively with poorly differentiated tumours, compared to 13.6% and 9.2%, respectively with well-differentiated SCC.¹⁴ When metastasis occurs it is usually to regional lymph nodes, and usually occurs 1–3 years following diagnosis and treatment. Recurrence of the primary lesion often precedes the development of metastasis. Features on histopathology associated with poorer prognosis include tumour arising in prior scar, tumour size >2 cm, depth of invasion >2 mm, desmoplastic reaction surrounding infiltrating keratinocyte islands and perineural or intravascular involvement. High-risk sites for local recurrence and metastasis are the ear and lower lip, respectively (Table 10.2).¹⁵

Dermoscopic findings of SCC include white circles, keratin, blood spots and white structureless zones. These findings may also be seen in keratoacanthoma.¹⁶

Classification

Cutaneous SCC can be broadly divided into *in situ* and invasive disease. SCCIS or Bowen's disease has not crossed the basement membrane and therefore does not have metastatic potential. Invasive cutaneous SCCs are classified by the degree of differentiation they show. Well-differentiated SCCs often demonstrate classic hallmarks of squamous differentiation, including scaly hyperkeratosis and/or the presence of keratin horns. KA is considered to be a form of well to moderately differentiated SCC that typically occurs in the elderly. Poorly differentiated lesions

Figure 10.6 (a) Actinic changes in the face of an elderly female. A crusty actinic keratosis (AK) is present over her right zygomatic arch, Bowen's disease (SCCIS) is present over her right zygomatic arch. (b) A keratoacanthoma (KA) developed quickly on the dorsum of the hand of this elderly woman. A central keratin plug is evident with surrounding elevated erythematous skin reaction. (c) Well-differentiated SCC on the helix of the ear. Ear SCCs are at high risk for metastasis. (d) Moderately differentiated SCC of the leg with central ulceration and surrounding crust. (e) Moderately to poorly differentiated SCC of the scalp with ulceration and recurrent bleeding. (f) A Marjolin's ulcer developing at the site of chronically unstable scar from extensive burns and skin grafting over 20 years before.

Figure 10.7 Representative histopathology specimens. (a) Bowen's disease (*in situ* SCC/SCCIS) demonstrating atypical cells arranged in nests or single cells involving the full thickness of the epidermis but not invading the dermis. (b) Moderately differentiated SCC with nests of atypical squamous cells infiltrating the dermis.

Table 10.2 High-risk factors for squamous cell carcinoma recurrence and metastasis

Risk factors	
Clinical	Tumour size >2 cm diameter Location: ear/lower lip/template/anogenital Arising in prior scar Immunosuppression
Histological	Poorly differentiated Depth >2 mm or Clark level ≥4 Desmoplastic reaction surrounding infiltrating keratinocytes Perineural or intravascular invasion

usually do not demonstrate much in the way of squamous differentiation and may be difficult to distinguish from other forms of cutaneous malignancy without immunohistochemistry. The other features used in SCC classification include size, location, lymphovascular or perineural spread and specific subtypes of SCC. Lesions under 2 cm in diameter arising with AK or associated with HPV, that are well-differentiated and do not demonstrate lymphovascular or perineural spread, usually have the best prognosis among invasive forms of SCC. Immune suppression, anatomic location on the lower lip, the ear, temple or anogenital region or the development of invasive disease from an SCCIS all carry a worse prognosis.

Cutaneous SCC of the lower lip arises inferior to the wet–dry border of the vermillion and therefore is managed as a cutaneous SCC. SCC arising in chronic wounds and/or scars (Marjolin's ulcers; Figure 10.6f) also pose a higher metastatic risk.

There are a number of rarer subtypes of SCC with varying prognosis. Spindle cell SCC (if not associated with irradiation) is of lower risk. Adenoid (acantholytic) SCC poses a more intermediate risk and adenosquamous carcinoma is a

higher risk tumour. Other subtypes can have varying degrees of risk, including SCC arising in adnexal cysts, clear-cell SCC, squamoid eccrine ductal carcinoma, follicular SCC and papillary SCC.¹⁷

Staging for basal cell carcinoma and squamous cell carcinoma

The American Joint Committee of Cancer (AJCC; Table 10.3) use the TNM classification system to stage both BCC and SCC. This system combines grades within each of the T, N and M components to produce a combined stage. Staging is divided by anatomic site and then into clinical (c) and pathology (p) stages. The eyelid, vulva and penis have separate classification systems to the rest of the skin due to their thinner skin and proximity to the brain, urogenital system/pelvis and large vascular structures, respectively. We will discuss the staging for the general skin.

Clinical stage (c) is the presumed staging based upon physical examination, medical imaging and biopsy results from the primary tumour and/or fine needle aspiration (FNA) cytology (with or without ultrasound guidance) of clinically involved nodes. Pathology staging (p) is the staging based upon the 'excisional' biopsy, including nodal basins if suspected of being involved. CT scanning with contrast is the most widely used imaging modality for advanced cases of NMSC. It gives good detail about the sites and size of involved nodal groups, provides definitive evidence of bony invasion and gross perineural involvement by demonstrating widening of foramina that transmit nerves. Positron emission tomography (PET) scanning can be combined with CT to increase sensitivity and specificity, but it is only effective for PET-avid tumours. The value of PET imaging in BCC is limited. Approximately half of BCCs are PET-avid (in small series in head and neck BCC) with the nodular type most likely to show fluorodeoxyglucose (FDG) uptake. PET can be very useful in SCC and occasionally

Table 10.3 The American Joint Committee on Cancer (AJCC) TNM system for basal and squamous cell carcinomas of skin (excluding eyelid, vulva and penis)

Component grade	Tumour (T0–4)	Lymph nodes (LN) (N0–3)	Metastasis (M0–1)
0	No evidence of primary tumour	No spread to LN	No spread to distant organs
is	Carcinoma <i>in situ</i> (confined to the epidermis)		
1	≤2 cm in longest diameter and has ≤1 high-risk feature ^a	Spread to 1 ipsilateral LN and is ≤3 cm in diameter	Spread to distant organs
2	>2 cm in longest diameter OR Any size with ≥2 high-risk features ^a	Spread to (a) 1 ipsilateral LN and is >3 cm but ≤6 cm in diameter or (b) >1 ipsilateral LN, ≤6 cm in diameter or (c) bilateral or contralateral LN ≤6 cm in diameter	
3	Any tumour size + LN OR Tumour extension to facial bones	Spread to any LN >6 cm in diameter	
4	Tumour extension to other bones or into base of the skull		

^aHigh-risk features include: depth >2 mm, invasion into reticular dermis or subcutis, perineural invasion, tumour on ear or non-hair-bearing lip, poorly differentiated or undifferentiated on histology.

demonstrates more soft tissue involvement than what was detected by PET alone. MRI is the imaging modality of choice to identify the extent of soft tissue involvement, including perineural involvement with thickening of nerves. This is especially important in tumour types such as SCC that demonstrate skip lesions (haematogenous spread) along nerves. Mutational profiling for p16, otherwise known as cyclin-dependent kinase inhibitor (a tumour suppressor gene) is principally used in oropharyngeal, perianal SCC as it is related to human papillomavirus status in these cases and has not found a role in cutaneous SCC currently.

The key points in the AJCC staging system are that stage and T level correlate (i.e. T4 lesions are stage 4) unless an N or M level upgrades the stage. Stage 1 and 2 are for T1 and T2 lesions (respectively) with no nodal involvement of distant metastases. Stage 3 and above indicates a T3 lesion or any nodal involvement. Stage 4 is for advanced T stage (T4), advanced nodal disease (N2 or above) or any distant metastases (M1).

Overall stage

Information from the stage categories is grouped together to provide the overall tumour stage.

- Stage 0: T0/is, N0, M0
- Stage I: T1, N0, M0
- Stage II: T2, N0, M0
- Stage III: T3, N0, M0 or T1 to T3, N1, M0
- Stage IV: T1 to T3, N2, M0 OR Any T, N3, M0 OR T4, any N, M0 OR Any T, any N, M1

Management

Staging permits an appropriate assessment of the severity of tumour invasion and whether a multidisciplinary team approach is necessary. Advanced skin cancer can be complex and present significant on-going treatment, management and surveillance problems that require a team approach to care. Luckily, the vast

majority of cutaneous SCCs are low grade at the time of diagnosis. In general, those with *in situ* disease or circumstances that prevent definitive excision may be treated with topical therapies, whereas more invasive disease requires surgical management. Treatment of SCC depends largely on assessment of risk of tumour recurrence or metastasis (Table 10.4). Non-surgical treatments can also be used as a neoadjuvant to reduce tumour size prior to excision. Close follow-up is necessary for all patients, as those who develop recurrence typically do so within 2 years of initial treatment.

Medical

Topical therapy

Cryotherapy is a quick and cost-effective method of treating SCCIS with a single 30 s freeze, achieving a clearance rate of 100% and a recurrence rate of 0.8% over a six-months to 5-year follow-up period in one large study. Overall, freeze times, number of cycles, clearance (50–100%) and recurrence (0.8–36.1%) rates are variable.¹⁸ Adverse events include blistering, scarring and hypopigmentation. This should not be used to treat invasive SCC.

Topical imiquimod 5% cream used for SCCIS (5/week for 16 weeks) resulted in a 73% clearance rate, with no recurrence after nine months of follow-up. 5-Fluorouracil once or twice daily demonstrated clearance in 69% and 93% of tumours after 4 weeks and 8 weeks, respectively, with a recurrence rate of 21% at 2 years.¹⁸ Adverse events include erythema, pruritus and pain. These agents cannot be used to treat invasive disease.

Topical diclofenac 3% gel has been approved for the treatment of AK but only a few studies have demonstrated clearance of SCCIS lesions. Diclofenac inhibits cyclooxygenase-2, which is upregulated in NMSC lesions, therefore it inhibits angiogenesis and induces apoptosis. Further research is required to determine its long-term efficacy and optimal dosing regimen.

Table 10.4 Treatment options for squamous cell carcinoma

Treatment modality	Ideal indication
Topical	
Cryotherapy, imiquimod, 5-fluorouracil, diclofenac ^b	SCCIS
Oral	
Capecitabine, cetuximab, erlotinib, gefitinib, interferon	Reduce incidence of SCC in organ transplant patients. Locally advanced and metastatic BCC. Neoadjuvant use prior to surgery to reduce surgical defect size of all subtypes SCCIS
Photodynamic therapy	Primary SCCs in those unwilling or unable to undergo surgery; adjuvant therapy post surgery for high-risk SCC; palliation; SCC of external auditory canal
Radiotherapy	
Procedural	
Standard excision	Suitable for majority of cutaneous SCC, clearance may not be as good as MMS in high-risk SCC in head and neck
MMS	High-risk SCCs in the head and neck ^a
Electrodessication and curettage	Low-risk, small (<1 cm), well-differentiated primary SCCs. SCCIS

^aHigh-risk: tumour diameter >1 cm, invasive (>6 mm deep) or aggressive histology, perineural, bone or muscle invasion, poorly defined clinical margins, prior site radiation or scarring, recurrent large SCC or immunosuppressed host.

^bLong-term follow-up outcomes still awaited. SCCIS, squamous cell carcinoma *in situ*.

Oral therapy

Capecitabine is an oral prodrug converted in the body to 5-fluorouracil (5-FU) and has demonstrated efficacy at low dose in the reducing the incidence of SCC in patients with solid organ transplants. Adverse events include fatigue, nausea, gout, hand-and-foot syndrome and poor renal function. Its optimal dosing regimen and use in non-organ transplant patients are yet to be established.

Approximately half of advanced SCCs contain *EGFR* mutations, which may lead to a more aggressive phenotype. Activation of *EGFR* stimulates keratinocyte proliferation and leads to resistance to apoptosis. Cetuximab, a monoclonal antibody against the *EGFR*, is FDA-approved for the treatment of recurrent or metastatic SCC of the head and neck. Additional treatments include interferon, erlotinib and gefitinib, which have been employed with various results. These treatments may be indicated in high-risk SCCs, which may require formal staging with CT and MRI to detect perineural involvement and sentinel lymphadenectomy in cases where lymph node involvement is suspected.

Photodynamic therapy

PDT can be used for SCCIS, in patients with multiple lesions or in poor surgical candidates (either unable or unwilling to undergo surgery). Clearance rates for SCCIS range from 84% to 96%, and recurrence rates vary from 0.5% to 31%. PDT is not

recommended for invasive SCC due to higher recurrence rates (up to 84% for invasive tumours) and risk of metastasis.

Radiotherapy

External beam therapy can be used for primary SCC treatment in those who are poor surgical candidates, as an adjunct treatment modality to surgery or as palliative treatment for symptomatic relief. Radiotherapy is useful in SCC because it semi-selectively targets rapidly dividing cells. Moderately to poorly differentiated (G3 and G4) tumours are often rapidly dividing and are more likely to demonstrate lymphovascular and perineural invasion and therefore radiotherapy helps control of the field and distant sites. However, when patients present late with advanced stage G1 and G2 tumours it can be challenging to treat them adequately with radiotherapy alone. Similarly, patients who do not complete their course of radiotherapy, select for more radio-resistant clones within their tumours and thereby decrease the effectiveness of radiotherapy for further dosing should this be required into the future. The use of adjuvant radiotherapy in high-risk SCC reduces the risk of local recurrence and improves overall disease-free survival. Despite the risk of hearing loss, it is particularly useful for SCCs of the external auditory canal. Ionizing radiation should be avoided in those with BCNS and XP.

Procedural

Standard surgical excision

Standard excision is the most widely used treatment options for invasive SCC. A 5 mm clinical margin removes almost 95% of low-risk SCC lesions.¹⁹ A wider margin up to 1 cm is used for more advanced lesions (e.g. >2 cm diameter, poorly differentiated SCC). DRAPE¹⁰ is used when there is uncertainty about the margin so formal histopathology assessment is awaited (with the excision site being dressed or skin grafted) prior to formal reconstruction. In advanced cases, the additional margin can provide added safety due to the risk of missing non-contiguous/in-transit metastases or skip lesions indicative of haematogenous spread and often does not change the type of reconstruction used (as seen in Figure 10.8a–d).

Mohs micrographic surgery

Mohs surgery offers the potential to achieve complete tumour resection while preserving as much healthy tissue as possible. However, Mohs surgery is time and resource expensive, requires specialized equipment and training and, as such, is poorly suited to managing the vast majority of cutaneous SCCs in our ageing populations. Case series demonstrate a lower local recurrence rate than with other modalities, with one series showing a cure rate of 92% at 4-year follow-up. MMS is considered by many to be the treatment of choice for high-risk lesions in the head and neck (Figure 10.9) where there is an increased chance of recurrence (lip, ear, nasal tip, eyelid, nail bed and anogenital area) but no controlled, clinical trial has been undertaken to permit direct comparison with standard surgical excision to date. Additional

Figure 10.8 (a) An advanced fungating SCC infested with maggots and invading the frontal bone and the dura of the frontal lobe of the brain. There was no systemic disease evident on imaging or clinical examination so using a multidisciplinary approach, the tumour was resected with the globe en-bloc (b), the remaining defect can be seen with exposed brain (c) before reconstruction in layers for dura through to a vertical rectus abdominus myocutaneous flap for defect coverage (d). The patient had postoperative radiotherapy and continued to be followed up in a multidisciplinary setting (specialized nursing, ENT, neurosurgery, plastic and reconstructive surgery, radiation oncology and opinions from specialist head and neck medical oncologists and radiologists).

indications for MMS include tumour diameter >1 cm, invasive (>6 mm deep) or aggressive histology, perineural, bone or muscle invasion, poorly defined clinical margins, prior site radiation or scarring, recurrent large SCC or immunosuppressed host.

Electrodessication and curettage

Electrodessication and curettage has been demonstrated to be as efficacious as standard surgical excision in the treatment of low-risk, small (<1 cm), well-differentiated SCCs,²⁰ unless there is great concern over location risk and immune status. Recurrence rates vary with physician experience between 2 and 18.8% over 1–5 years follow-up.

Notes on reconstruction

Appropriate management of NMSC should follow sound oncology principles, including the establishment of the definitive diagnosis through biopsy, adequate staging, identification of

involved structures and complete tumour clearance where this is the goal. Sometimes it is not possible to cure the patient, but surgical or adjunctive therapies are used to remove tumour deposits that are symptomatic due to persistent bleeding or ulceration, sometimes referred to as a 'toilet' procedure to assist in daily cares. If a single treatment modality is most likely to be effective long term, then this modality is the treatment of choice in most cases, depending on a risk–benefit profile for the patient. It is essential to have a clear perspective of what the goal of any treatment is and be clear about this and the likely defect with the patient. It is not enough to just render the patient tumour-free. There should also be a plan for how to restore form and function. It is important to consider what should be done if the tumour is more advanced or has regressed upon presentation for treatment. In some cases, it is very obvious that a multidisciplinary approach is necessary (e.g. Figure 10.8). A patient-focused approach combined with further development of targeted therapies offers significant hope to further reduce the morbidity and mortality of NMSC in our rapidly ageing populations.

Figure 10.9 High-risk zone for SCC where Mohs micrographic surgery is most suitable.

³The University of Melbourne Department of Surgery, Melbourne, Australia

Introduction

The atypical skin lesions are a diverse group of tumours that are uncommon but clinically important. They include a spectrum from benign lesions through to those that demonstrate local invasion and/or distant metastatic potential. Since these lesions are only seen infrequently during clinical practice, it is important to have a solid grounding in the general principles of their management. We also cover some common surgically relevant lesions of the skin including common types of cysts. A clear understanding of cysts and their aetiology is important to direct their management. We have divided the atypical lesions into benign or malignant and then by their cell/tissue of origin to provide a framework for their study. Such a framework is not perfect due to our evolving understanding of the molecular and cellular bases of these tumours, but it provides a foundation for their study.

Benign lesions

Benign lesions are clinically important for several reasons. They can be confused with malignant lesions, be symptomatic due to their size, appearance, location, irritation and bleeding or may undergo malignant transformation. Knowledge of the uncommon benign lesions can also provide a means to understand their malignant counterparts. Such knowledge is invaluable to the surgeon when examining the correlation between the clinical presentation and the histopathologic diagnosis. Any discrepancy between these two should prompt the surgeon to seek clarification and/or a second opinion regarding the histopathologic diagnosis. Good communication between the surgeon and the histopathologist is essential for good care.

Cysts

True cysts are defined as epithelial-lined 'fluid-filled' spaces and are relatively common in clinical practice. There can be many names for various cysts, including a 'wen', and often terms are incorrectly applied in general usage.

Epidermoid cysts (keratin cysts)

These common cysts enlarge subcutaneously but maintain a connection to the overlying skin at their punctum. Lined by squamous epithelium, they produce soft keratin that fills the cyst with a waxy/cheesy material. Although often called sebaceous cysts, this is a misnomer as they do not contain sebum. True sebaceous cysts are uncommon, arising from the sebaceous glands. There are two types of epidermoid cyst. Epidermal inclusion cysts result from the inoculation of squamous epithelium into the dermis during trauma (e.g. body piercing). Infundibular cysts specifically arise at the infundibular portion of the hair follicle, but are otherwise clinically the same.

Management depends upon their state at presentation. Patients typically present with them either as non-tender lumps attached to the undersurface of the skin or when they become infected. Surgical excision in quiescence is ideal, but must include excision of their attachment to the overlying skin (the punctum). Significant compression can cause a release of keratin through the punctum, but this also increases the risk of infection. In infection, decompression of the cyst abscess, removal of the cyst material and curettage of the cyst lining allows resolution of the infection and often reduces the size of the lesion down to a small scar. Curettage is associated with a significant risk of recurrence because of its inability to ensure complete removal of the lining of the cyst. Once the scar has settled appropriately, the scar, remaining cyst and its punctum can be removed to stop recurrence. Uncommonly, they spontaneously resolve by becoming marsupialized and discharging.

Tricholemmal (pillar) cysts

Tricholemmal cysts are similar to epidermoid cysts except that they specifically arise from the outer root sheath of hair follicles. They typically arise in the scalp as this has the highest density of hair follicles. They are usually multiple and the tendency to form tricholemmal cysts runs in families. Surgical excision is the treatment of choice and when excised with the overlying hair follicle, recurrence is unlikely. On histology, they can demonstrate areas of nuclear atypia, mitotic figures and dyskeratosis

and therefore be confused with squamous cell carcinoma (SCC), but it is rare for them to undergo malignant transformation.

Dermoid cysts

Dermoid cysts are hamartomas, often containing multiple epithelial derivatives (skin, hair, etc.). They are found in numerous organs and regions of the body. In the skin they are often near the midline or in the head and neck along tissue fusion planes and therefore can have connections to deep structures such as underlying bone. Their superficial position and hamartomatous origin make them a lesion of childhood (present at birth, but enlarging post nately). They can be associated with other conditions (epibulbar dermoids and Goldenhar syndrome). Excision of the cyst with any communications to underlying structures is effective to prevent recurrence.

Benign lesions associated with epidermis

Acrochorda

Acrochorda (acrochordon = singular) or skin tags are fibroepithelial polyps that appear as raised, smooth or irregular-surfaced pieces of skin on a small stalk called the peduncle. Nearly half of the adult population has at least one near skin creases in the neck, axilla, groin, breasts and eyelids. Shear forces of skin on skin are thought to be their underlying cause and therefore they are common in obesity. Female gender, human papilloma virus 6 and 11 and familial tendency are all thought to predispose to them. They may be symptomatic due to irritation from clothing or jewellery or when they bleed because of tractional injury. Acrochorda are usually small (2–5 mm) but occasionally larger. They are composed of a fibrovascular core and adipose tissue covered by normal skin. Numerous treatment modalities are available from ligation to cryotherapy and simple surgical removal, but the patient must be aware of their risk of further lesions.

Warts

Warts are focal (verrucous) keratinized lesions caused by human papilloma virus (HPV). The virus replicates in the stratum granulosum, inducing underlying basal keratinocytes to proliferate, causing a hyperkeratotic response. They may appear raised, flat, filiform, cauliflower or ingrown (e.g. plantar warts) and can also occur under or around the nails. Over 150 different types of HPVs have been characterized but typically, only 1–2 strains cause each normal variant (verruca vulgaris HPV 2 and 4, cauliflower/Butcher's warts HPV 7, palmoplantar warts/myrmecia HPV 1, flat warts HPV 3 and 10).¹ These are distinct from the HPV strains associated with genital warts (HPV 6 and 8) and those producing an increased risk of intraepithelial neoplasia or invasive tumours affecting the vulva, penis, cervix or oral cavity (HPV 16 and 18).² Warts may be singular or multiple with a predilection for the hands due to contact transfer. Wart infections are self-limiting and resolve once the host mounts an immune response to the virus. Surgical excision produces some release of human papilloma virions, but topical therapies are a less invasive approach to induce an immune response.

Therapy is largely divided into management of the hyperkeratosis and induction of a suitable immune response. Hyperkeratosis management can be undertaken by multiple means, including use of salicylic acid (3–60%, daily or twice/day), occlusive dressings, cryotherapy and shaving by scalpel or sharp curette.

Topical therapies to promote an immune response include podophyllin (resin or toxin), formalin (3% solution), imiquimod (Aldara), retinoids such as tretinoin and 5-fluorouracil (5-FU). Podophyllin is available over the counter in most countries and can be applied without specific training. Other approaches that have been used include laser therapy, intralesional agents (bleomycin and interferon alpha) and topical allergens or caustic agents. Although usually successful, they have significant potential side effects not found with the mainstream therapies above. Patient education usually helps to avoid surgical intervention and scarring. Histologically, warts demonstrate koilocytes (vacuolated cells with viral infection) and hypergranulosis with columns of parakeratosis and compact orthokeratosis. Typically, the marked hyperkeratosis and papillomatosis are associated with elongated rete ridges sloping inwards to the centre of the lesion.

Malignant transformation is sometimes seen in long-standing immune suppression, but it is unclear to what degree HPV infection contributes because the patients already have increased risk of skin cancers. Epidermodysplasia verruciformis (Lewandowsky–Lutz dysplasia) is a rare autosomal recessive skin disorder that increases the susceptibility to HPV infections. These patients have a very high risk of skin cancer due to the increased risk of malignant transformation of their lesions.

Benign lesions associated with hair follicles

Pilomatrixoma

This is a benign appendageal tumour that typically occurs in the head and neck region and demonstrates differentiation towards hair (follicular) cells. Although considered a tumour of children, they can occur in adults. They are associated with a mutation in the *CTNNB1* gene and although familial cases have been observed, the mode of inheritance has not yet been established. In addition to sporadic cases, they may be associated with Gardner syndrome (familial colorectal polyposis), myotonic dystrophy (especially if multiple lesions) and sarcoidosis.

Pilomatrixomas present as firm nodules that are usually solitary and asymptomatic, but occasionally associated with local pain if infected or inflamed. Usually slow-growing, they can be confused with other skin lesions, including nodular basal cell carcinoma (BCC), despite their deep position in the lower dermis or underlying adipose tissue. Lesions often contain calcium deposits that are visible on medical imaging. Pilomatrix carcinoma is well documented but very rare.

Histology demonstrates irregular islands of epithelial cells surrounded by a connective tissue capsule that produces a diffuse lesion in most cases. The epithelial cells are divided into basophilic (germinal) cells around the periphery and shadow

cells (anucleated) centrally, in keeping with a hair-like process. Chronic lesions have fewer basophilic cells and calcium deposits can be visualized through the use of special stains (von Kossa). The diffuse nature of most lesions leads to a greater risk of local recurrence unless a wide local excision is performed (1 cm or greater). Mohs micrographic surgery has been trialed to minimize resection of uninvolved tissue, but its effectiveness remains unclear relative to standard surgical excision.

Trichoepithelioma

Trichoepithelioma is a tumour of the hair follicle and adnexae that is often confused with BCC (Figure 11.1). They typically arise as single or multiple as small (<1 cm), firm round lesions on the face before or after puberty that may display pearly. The lesions form a basic hair follicle but no hair shafts and may have a different surface colour depending on their site of origin. Solitary lesions are typically sporadic, but a familial (multiple) form of

trichoepithelioma has been associated with mutations on chromosome 16q21 (Brooke–Speigler syndrome).³ Trichoepitheliomas are composed of nests of basophilic cells often arranged like a hair follicle but they do not display the surrounding myxoid stroma or perineal clefting found in BCC. A desmoplastic variant commonly forms an annular shape that can be confused with BCC and has a marked desmoplastic surrounding response on histology. Simple surgical excision of all forms without a significant margin is usually effective in preventing recurrence.

Trichofolliculoma

Trichofolliculomas arise directly from hair follicle tissue. They are uncommon small solitary nodules found around the face of adults. A central pore may express sebum and/or hair. They are thought to arise from hamartomatous rests of stem cells that show incomplete differentiation towards hair follicles, as supported by the prominence of Merkel cells within the follicular

(a)

(b)

(c)

Figure 11.1 (a) Multiple trichoepitheliomas within the V1 dermatome in a 6-year-old girl. No relatives had Brooke–Speigler syndrome and therefore this may have been the result of a sporadic mutation. The main cluster was treated by simple excision. (b) Histopathology demonstrates nests of basaloid cells (without clefting) throughout the dermis with keratin microcysts. There is recapitulation of primitive hair bulbs, but no epidermal connection. (c) Desmoplastic trichoepithelioma demonstrating a 'paisley-tie' pattern of strands and cords of basaloid cells, keratin microcysts, microcalcification and stromal fibrosis.

epithelium in these lesions.⁴ Their central follicle may have secondary or tertiary follicles and hair shafts may be present within the follicle lumen on histology, helping to distinguish them from trichoepitheliomas, along with a prominent surrounding stroma. There is a sebaceous variant where the central follicle has well-differentiated sebaceous lobules emptying into it. They are considered benign with only a single case of perineural invasion ever reported.⁵

Tricholemmoma (trichilemmoma)

Tricholemmoma is an uncommon benign tumour arising from the outer root sheath of hair follicles. It appears as a warty or smooth papule on the face and neck region and when multiple lesions are present, and it is diagnostic of Cowden syndrome (hamartomatous intestinal polyposis with multiple tricholemmoma lesions). Cowden syndrome demonstrates autosomal dominant germline inheritance associated with mutations of the tumour suppressor gene *PTEN* (phosphatase and tensin homolog) located on chromosome 10q23.3⁶ but other mutations are occasionally found (e.g. *BMPRIA*). *PTEN* is negative in sporadic tricholemmomas, but often positive in Cowden syndrome, presumably due to a loss-of-function mutation. On histology it appears as lobular downward growths of epidermis and is often surrounded by a hyaline band or thickened basement membrane. Clear cells or cells with prominent vacuoles are typically present (glycogen) and the lobules demonstrate peripheral palisading.

Benign lesions associated with sebaceous glands

Sebaceous hyperplasia

Sebaceous hyperplasia is a common condition characterized by single or multiple soft small papules on the face, neck and occasionally chest in middle-aged to elderly individuals. Most common on the forehead, nose and cheeks, it presents with raised yellowish areas around a central follicular ostium. It can also affect the areola, penis, vulva and oral mucosa.⁷ Rhinophyma is considered by many to be a severe variant of sebaceous hyperplasia, but has closer linkages with acne rosacea. The pathophysiology relates to the effect of androgens on sebaceous glands. Androgens drive sebocyte turnover and with advancing age, androgen levels drop and sebocyte turnover slows down, resulting in overcrowding by primitive sebocytes that do not contain much sebum. As a result, the glands enlarge with a large number of immature cells. There is no malignant transformation potential, but they may be associated with skin cancer in transplant patients.⁸ Sebaceous hyperplasia does not normally require any treatment, however patients may present due to aesthetic concerns or because the lesions may be confused with BCC. Treatment options are manifold, including cryotherapy, photodynamic therapy, chemical peels, laser therapy (CO₂ or pulsed-dye), shave excision or formal excision, but all of these are associated with varying degrees of scarring and/or pigmentation changes. Oral retinoids (e.g. isotretinoin) have been used with some success,

but sebaceous hyperplasia can recur upon cessation of therapy⁹ therefore they are only indicated for severe disfiguring sebaceous hyperplasia.

Benign sebaceous adenoma

A benign neoplasm with a well-differentiated sebaceous pattern that presents as a slowly enlarging smooth, sometimes yellow papule with a central depression on the face and scalp. It can readily mimic BCC and is distinguishable from sebaceous hyperplasia histologically by a higher turnover of sebocytes, good differentiation of these cells and because it is often mixed with other pilosebaceous components (e.g. hair). Benign sebaceous adenoma is the benign end of the spectrum of neoplasms involving sebaceous differentiation. Sebaceous neoplasms as a whole can show variable degrees of differentiation (from well to poorly differentiated) and a mixture of differentiation patterns based on the close proximity of the sebaceous gland with the pilosebaceous unit (hair, sebaceous and apocrine sweat glands). Lesions can be either solitary or multiple and, when multiple, may be associated with systemic conditions (e.g. Muir-Torre syndrome – internal malignancy with multiple sebaceous adenomas or sebaceous neoplasms).

Naevus sebaceous of Jadassohn

This is a well-circumscribed benign lesion presenting as a yellow to light brown velvety or papular plaque on the scalp and face of children or young adults (Figure 11.2). In addition aesthetic considerations, naevus sebaceous is important because it carries a risk of transformation to other tumours and can be associated with neurological phenomena as part of sebaceous naevus syndrome. Lesions may be present at birth, but typically get larger before or around puberty. Some lesions have a *PTCH* gene mutation, but most are considered to have a mosaic genetic abnormality. Naevus sebaceous is relatively unusual among the epidermal naevi because it often contains all skin components including epidermis, sebaceous and apocrine glands, connective tissue and primitive hair follicles. Therefore it is sometimes called an organoid naevus and can transform into numerous tumours both non-malignant (e.g. syringocystadenoma papilliferum, trichoblastoma or tricholemmoma) or more commonly malignant (10–30% lifetime risk of BCC or other malignant tumours). If a focal area of change develops within a sebaceous naevus, this should be biopsied to exclude malignant transformation, and patients and their families should be advised to monitor the lesions for such changes.

Rarely, patients with very large lesions can experience neurological disorders such as epilepsy. When these neurological disorders are more marked, including a combination of seizures, developmental delay, cranial nerve palsies and/or hemiparesis and structural abnormalities of the brain, the constellation is referred to as naevus sebaceous syndrome. Naevus sebaceous is well-circumscribed and therefore amenable to excision with a minimal margin and most practitioners would advise removal by teenage or early adult life.

Figure 11.2 (a) Naevus sebaceus (of Jadassohn) of the scalp in an 11-year-old child, managed by simple excision. (b) Histopathology demonstrating epidermal naevus-like epidermal hyperplasia, increased sebaceous glands associated with alopecia and ectopic apocrine glands in deep dermis (bright pink staining). (c) The other end of the same lesion showing a junction with a syringocystadenoma papilliferum (right), (d) a benign apocrine neoplasm commonly associated with naevus sebaceus that has apocrine cells demonstrating 'decapitation' secretions.

Benign lesions associated with apocrine glands **Hidradenoma papilliferum**

This is a benign cutaneous tumour derived from apocrine tissue that most commonly presents in the vulval region of middle-aged women, but can appear at extravulval sites in both sexes. Lesions appear as round, domed nodules that may ulcerate. On histology, they are identical to intraductal papillomas of the breast and therefore are considered to be ectopic breast tissue. They have a complex papillary structure showing an inner layer of PAS-positive columnar/cuboidal epithelium, a basal layer of myoepithelial cells that are S-100 positive and a fine fibrovascular stroma.

Poroma

Poromas are benign adnexal neoplasms of epithelial cells that display ductal (usually distal) differentiation. Although often described as 'eccrine poromas', the majority are thought to be

apocrine in origin. They present as solitary (<2 cm) skin-coloured papules or nodules that may be mistaken for other lesions or develop within naevus sebaceus. Typically asymptomatic, they can cause pain on ulceration or on the sole of the foot. Simple surgical excision is the treatment of choice because it is usually curative and provides suitable specimens for histopathology.

Benign lesions associated with sweat ducts **Syringoma**

This is a benign adnexal tumour that typically presents as single or multiple small (<3 mm) skin- or yellow-coloured dermal papules usually around the eyelids, penis or vulva. They affect 1% or less of the adult population and are usually the result of benign growth of eccrine sweat gland elements or eccrine differentiation of pluripotent stem cells. Four variants have been recognized:¹⁰

localized, Down syndrome associated, generalized/multiple (including eruptive syringomas) and familial variant.

On histology, they are a superficial dermal lesion characterized by abundant small ducts with a double-cuboidal epithelial lining and a sclerotic surrounding stroma. A PAS-positive secretion is present within the ductal lumen and the classic comma-shaped appearance of ducts on this lesion represent ducts that have elongated tails of epithelial cells upon sectioning. There are multiple management options from simple excision through electrocautery, cryotherapy, laser therapy, topical agents, topical or systemic retinoids. Simple excision with minimal margin achieves a definitive histopathology diagnosis (to exclude BCC) and can produce minimal scarring. Scar burden increases with the number of lesions present and therefore there is no perfect treatment for large numbers of lesions.

Cylindroma

Cylindromas are benign adnexal tumours (apocrine or mixed) that present as single or multiple lesions in the head and neck. When single, they are typically sporadic occurring from middle age onwards as slow-growing, rubbery nodules that may reach up to 5–6 cm in size. Mutations in the *CYLD* gene (16a12–q13) are the principal cause of multiple cylindromas and may indicate familial inheritance (Brooke–Spiegler syndrome – an autosomal dominant syndrome with variable penetrance).¹¹ Cylindromas may have a similar origin to related tumours such as spiradenomas and trichoepitheliomas because mixed lesions have been reported. Definitive diagnosis is by biopsy. Histology demonstrates a dermal tumour with islands of basophilic cells demonstrating peripheral palisading, surrounding larger, more pale central cells. Lamina densa-like material (predominantly collagen IV) surrounds the islands and the nests to separate them from the dermal matrix and these often give the lesions a jigsaw-like pattern of polygonal or oval nest shapes. Spiradenomas are related lesions, but are distinct from cylindromas because they have lymphoid invasion. Management is typically through surgical excision, which is curative following complete excision.

Spiradenoma

These are benign, solitary tumours thought to be of apocrine origin that present on the upper, anterior half of the body as pink, red, purple or blue nodules up to 1 cm in diameter. They typically occur in 15- to 35-year-olds, although infantile cases (with superficial dermal nodules) have been reported. They can be episodically painful and while most are sporadic, they can be associated with Brooke–Spiegler syndrome (with trichoepitheliomas, cylindromas, spiradenomas and mixed lesions). Mutations in the *CYLD* gene on chromosome 9 have been associated with their development,¹¹ but spiradenomas also have increased expression of p53. Multiple, giant, linear and grouped forms have all been described. Malignant transformation can occur, particularly in long-standing lesions. Surgical excision is usually curative, but when multiple, radiotherapy and hyperthermic limb perfusion chemotherapy have been used successfully to avoid widespread excision.

Benign dermal tumours

Dermatofibroma

Dermatofibroma (or superficial benign fibrous histiocytoma) is a common cutaneous nodule of the limbs that is typically asymptomatic, but has been reported to be the most common atypical lesion causing pain.¹² Their aetiology remains unknown, but it may be trauma. Their prominent mast cells may release transforming growth factor beta (TGF- β) and other fibrinogenic factors to promote the fibrotic reaction seen histologically.¹³ Syndecan 1 and fibroblast growth factor receptor 2 (FGFR-2) have also been implicated in their formation.^{14,15} Lesions are usually solitary, but may be multiple. When numerous lesions are present (≥ 15) they may be associated with a systemic condition including immune suppression (e.g. HIV), autoimmune conditions (systemic lupus erythematosus (SLE), dermatomyositis, Graves' disease, Hashimoto's thyroiditis, myasthenia gravis), malignancies (leukaemia, myelodysplastic syndrome, cutaneous T-cell lymphoma, multiple myeloma), atopic dermatitis or Down syndrome.¹⁶

Dermatofibromas can be PET avid and may have a similar appearance to many other tumours. Dermoscopy can be useful to display an overlying peripheral pigment network with a central white area.¹⁷ Ultrasound may show a solid hypoechoic nodule. A biopsy is warranted if there is any diagnostic uncertainty. Surgical removal is indicated if lesions are symptomatic, aesthetically unacceptable or when diagnostic uncertainty remains. Excision of the tumour with minimal overlying skin is usually effective in preventing recurrence, but aggressive subtypes (aneurysmal, atypical, cellular, deep/subcutaneous) have a local recurrence rate of up to 20%.¹⁶ Rare cases of metastasis have been described with these variants.

Unusual malignancies of skin

The malignant tumours described in this section are uncommon at best and hence there is a paucity of high-level evidence to guide treatment. Accurate histopathology evaluation is vital and given the complexity and the rarity of these tumours, referral for expert review may be considered. Mohs micrographic surgery has been reported for many of these tumours, particularly in sites where obtaining a wide margin may be problematic. In general, lesions successfully treated by Mohs tend to be smaller and although results appear to be as good as standard wide surgical excision, the number of cases and/or length of follow-up are limited in most reported series. In cases where the completeness of excision is uncertain, DRAPE (delayed reconstruction after pathology evaluation)¹⁸ should be considered.

Merkel cell carcinoma

Merkel cell carcinoma (MCC) is an uncommon aggressive cutaneous malignancy that is increasing in frequency (Figure 11.3). The mnemonic AEIOU has been proposed to summarize the most common clinical characteristics (asymptomatic, expanding

Figure 11.3 (a) Merkel cell carcinoma arising in the anterior lower leg of a 72-year-old man. The lesion is raised and pink/purple in colour. (b) Histopathology showing an intensely basophilic, cellular dermal tumour. (c) Higher power view demonstrates nuclear moulding, minimal cytoplasm, numerous mitoses and apoptosis consistent with a 'small cell undifferentiated malignancy'. (d) Cytokeratin 20 (CK20) immunolabelling shows the perinuclear 'dot' of the Golgi apparatus and nuclear membrane.

rapidly, immune suppression, older than 50 years and UV-exposed site on fair skin).¹⁹ Correspondingly, the lesion affects the sun-exposed areas of elderly males, is related to chronic UV exposure and immunosuppressed patients are overrepresented. The cell of origin is unknown but is unlikely to be the Merkel cell, a mechanoreceptor found in skin. Almost all cases are associated with Merkel cell polyomavirus. The characteristic presentation is a rapidly growing firm non-tender flesh-coloured nodule. The most common site is the face (25%); the head and neck, trunk and limbs account for the remainder.¹⁹

The histological features are of a neuroendocrine tumour with three main patterns. Most common is the solid type, a densely blue (basophilic) tumour with paving of rapidly dividing tumour cells. The trabecular (cells arranged in cords or columns of invasive basophilic cells) and diffuse (poor cellular cohesion reminiscent of lymphoma-like tissue growth)

patterns are less common. The potential for coexistence of MCC within BCC or SCC must always be considered and can be especially difficult to diagnose in desmoplastic non-melanoma skin cancer variants. The diagnosis is confirmed by immunohistochemical labelling with cytokeratin 20 (perinuclear Golgi dot).

Staging of MCC

Prior to 2010, there were at least five competing staging systems in common use for MCC, limiting comparisons between centres worldwide. In 2010, the American Joint Committee on Cancer (AJCC) published a revised TNM staging system focusing on the size and degree of invasion of the primary tumour, whether micro, macro or in-transit disease is present regionally and the presence and site of distant metastases (Table 11.1). Preoperative staging should include fine-slice CT scans of the chest, abdomen

Table 11.1 American Joint Committee on Cancer staging for Merkel cell carcinoma²¹

T Staging for MCC	
Tx	Primary tumour cannot be assessed
T0	No evidence of primary tumour (e.g. metastasis with unknown primary)
Tis	<i>In situ</i> primary tumour
T1	≤2 cm maximal tumour dimension
T2	>2 cm but ≤5 cm maximum tumour dimension
T3	>5 cm maximum tumour dimension
T4	Primary tumour invades bone, muscle, fascia or cartilage
N Staging for MCC	
Nx	Regional lymph nodes cannot be assessed
N0	No regional node metastases or in-transit metastases
cN0	Nodes negative by clinical exam (no pathology nodal exam performed)
pN0	Nodes negative by pathology exam
N1	Metastases in regional lymph nodes
N1a	Micrometastasis
N1b	Macrometastasis
N2	In-transit metastasis
M Staging for MCC	
M0	No distant metastases
M1	Metastases beyond regional lymph nodes
M1a	Metastases to skin, subcutaneous tissues or distant lymph nodes
M1b	Metastases to lung
M1c	Metastases to all other visceral sites
Stage by TNM for MCC	
0	Tis, N0, M0
IA	T1, pN0, M0
IB	T1, cN0, M0
IIA	T2/T3, pN0, M0
IIB	T2/T3, cN0, M0
IIC	T4, N0, M0
IIIA	Any T, N1a, M0
IIIB	Any T, N1b/N2, M0
IV	Any T, Any N, M1

and regional lymph node fields with PET scanning if available. Not all MCCs are PET avid, especially if already irradiated.²⁰

Other poor prognostic indicators include age >70 years, male sex, truncal or head and neck site (especially lip), nodal or distant disease at presentation and adverse histopathology features (small cell size, infiltrative pattern, high mitotic rate, depth of invasion and lymphovascular invasion).²²

Management

Management remains controversial, particularly regarding the primary tumour. MCCs are highly sensitive to radiotherapy but current management recommendations are based on relatively small case series. Larger series typically suffer from a lack of uniform staging, treatment or follow-up. In general, surgical excision is favoured for small lesions in favourable sites. For larger lesions radiotherapy alone to the primary site may be more

appropriate. If concern remains about the completeness of margins after definitive surgery, adjuvant radiotherapy is indicated. MCCs demonstrate a marked propensity for lymph node spread, therefore sentinel node biopsy is recommended by many authorities, but the indications for its use remain unclear and significant false negative rates have been reported. Prophylactic management of the nodal basin is associated with significantly reduced regional recurrence.²³ The role for sentinel node biopsy is to identify the appropriate nodal basin and select patients for nodal irradiation or completion lymphadenectomy, which provide equivalent regional control. For tumours less than 10 mm in size the risk of lymph node involvement is less than 10%. For lesions greater than 20 mm the risk may be 40% or higher.²⁴ Sentinel node biopsy is reasonable for lesions larger than 10 mm although for smaller lesions, it may be justified where the tumour is thick, has lympho-vascular invasion, an elevated mitotic rate or the patient is young. Given the significant risk of developing distant disease in patients with lymph node involvement or tumours greater than 20 mm in size, adjuvant systemic chemotherapy (carboplatin and etoposide) concurrent with radiotherapy may be indicated, however many patients are elderly and therefore potentially unfit for such therapy.²⁵

Most recurrences occur within 2 years of diagnosis. Locoregional recurrence is not uncommon. Palliative chemoradiotherapy may have some benefit for locoregional and distant recurrence most commonly seen in liver, bone, lung and soft tissue.

Adnexal carcinomas

Malignant neoplasms of the pilosebaceous unit are very rare. They are classified with a bewildering array of terms, many of which are revised on a regular basis. The more common types include microcystic adnexal carcinoma, sebaceous carcinoma and porocarcinoma. Overall survival is approximately 70% at 5 years.^{26,27}

Microcystic adnexal carcinoma

Microcystic adnexal carcinoma (MAC) is an infiltrative tumour usually of the head and neck (particularly central face) in older persons. The presentation is usually innocuous as a slow-growing skin-coloured plaque. Wide excision is indicated as the extent of the tumour is often considerably more than the clinical examination would suggest. Properly managed, local regional or distant recurrence is rare. Radiotherapy may have a role when surgical excision is compromised or not possible.²⁸

Sebaceous carcinoma

This occurs predominantly in the head and neck in older patients with a predilection for the eyelid. If adequately excised, recurrence is rare.

Mohs surgery may have a role in managing this tumour, given its common involvement of the eyelid, but as with other unusual cutaneous malignancies, the evidence for its use is largely case series with few patients and/or relatively short follow-up.

Porocarcinoma

This arises not infrequently from a long-standing benign apocrine/eccrine poroma. Most involve the lower limbs in elderly persons as slow-growing lesions that increase their growth rate just prior to diagnosis. Lymph node involvement occurs infrequently. Sentinel node biopsy has been reported, however its use is still undefined. With wide excision, long-term survival is reasonable.²⁹

Extramammary Paget's disease

This is a rare tumour classified as an adenocarcinoma of apocrine glands but considerable debate remains about the cell of origin. The classic site is the perineum (vulva, penis, scrotum and perianal area). More rarely, the axilla and eyelid are affected. Up to one third of affected patients have an occult malignancy

(bladder, prostate, kidney, colon and rectum). Approximately two thirds of patients have *in situ* disease only (Figure 11.4).

The typical history is of a slowly progressive lesion (often mistaken for eczema or similar rash) in patients over 70 years. The disease is frequently extensive at diagnosis and may be multifocal. Careful examination, combined with punch biopsies to confirm the extent of the disease and the presence/absence of invasion are warranted for larger lesions. Exclusion of an underlying primary malignancy is appropriate.³⁰

Wide surgical excision with clear margins is the treatment of choice. Local recurrence may occur in up to 50% of patients. Lymph node involvement occurs in up to two thirds of patients with invasive disease. Sentinel node biopsy has been reported but its role is undefined. Lymph node involvement, dermal involvement and lymphatic and/or vascular invasion are poor

Figure 11.4 (a) Extensive extramammary Paget's disease (EMPD) with invasive adenocarcinoma developing in a 71-year-old male. The patient had a 'rash' for over 7 years. Extensive work-up failed to disclose any occult malignancy. (b) Histopathology demonstrates nested and single malignant cells in the epidermis, with malignant glands in the upper dermis (bottom right). (c) Nested and single malignant cells in 'Pagetoid' distribution in the epidermis. (d) Invasive adenocarcinoma (bottom) with *in situ* EMPD in the epidermis above.

prognostic factors. The role of radiotherapy is controversial. Radiotherapy as monotherapy may be appropriate when surgery is contraindicated however it is not clear if it is as effective as surgery. The literature is also unclear as to whether adjuvant radiotherapy after complete surgical excision offers major benefits. In patients with extensive *in situ* disease, topical imiquimod or photodynamic therapy have been used with relative success.

Overall survival at 5 years is 60% for patients with invasive disease. Long-term follow-up is recommended due to the significant risk of locoregional recurrence.

Other rare adnexal carcinomas

- Pilomatrix carcinoma occurs in the head and neck of females, probably from a benign pilomatrixoma. Wide excision is indicated.
- Malignant chondroid syringoma (malignant mixed tumour) occurs on the extremities and trunk, following an unpredictable course with spread to regional lymph nodes and distant sites. Wide excision is indicated.
- Hidradenocarcinoma occurs in the head, neck and extremities of elderly patients and pursues an aggressive course with regional and distant metastasis.
- Malignant cylindroma is a very rare tumour, probably arising from a benign cylindroma in older patients, which frequently metastasizes widely.
- Eccrine spiradenocarcinoma develops in elderly patients, usually from a pre-existing benign spiradenoma. Wide excision is usually curative as lesions rarely metastasize.

Soft tissue sarcomas of skin

Tumours of mesenchymal origin arising in skin account for less than 5% of all soft tissue sarcomas. Excluding Kaposi's sarcoma, dermatofibrosarcoma protuberans (DFSP) accounts for two thirds of cases. Leiomyosarcoma of the skin and cutaneous angiosarcoma account for an additional 20%. The remainder include fibrosarcomas, myxosarcomas and atypical fibroxanthoma (AFX). In general, these lesions are characterized as having low malignant potential with a significant risk of local recurrence.³¹ They present as small, innocuous-appearing, slowly growing skin lesions. Invariably the diagnosis is made retrospectively following biopsy. Lesions previously described as malignant fibrous histiocytoma (MFH) have been subjected to considerable revision in recent years. In many cases they have been reclassified using an alternative nomenclature – unclassified pleomorphic sarcoma (UPS). UPS is considered by many to be a final common phenotype for various undifferentiated tumours and therefore is reserved as a diagnosis of exclusion.³² Management of these lesions will not be considered further as they behave in a far more aggressive fashion as with MFH/UPS elsewhere. Wide resection with adjuvant radiotherapy is the usual primary management.

Dermatofibrosarcoma protuberans

Dermatofibrosarcoma protuberans (DFSP) is an uncommon, dermally derived tumour³¹ with a marked tendency to local recurrence (Figure 11.5). Haematogenous spread is uncommon

(<5% of cases) and lymphatic spread is rare. Approximately 90% of tumours are low grade, however the remaining 10% display higher grade sarcomatous transformation (most commonly fibrosarcoma). DFSP affects both sexes equally and is typically a tumour of the third and fourth decades, although paediatric cases have been described. Nearly half the tumours arise on the trunk, the proximal limbs approximately 40% and the head and neck accounts for the remaining 10–15%.³³

Most present as small, slow-growing, innocuous, indurated, skin-coloured plaques that may become raised, pink and eventually violaceous with telangiectasia over time. The lesion is attached to skin and advanced cases demonstrate the characteristic cutaneous nodules that give the tumour its name. Advanced lesions may ulcerate, bleed and become fixed to underlying structures. The more malignant form of DFSP, with fibrosarcomatous transformation presents in an identical fashion.³⁴ A less aggressive variant, the Bednar tumour more commonly seen in Black persons is an uncommon, pigmented form of DFSP (5% or less) where scattered melanosome-containing cells are seen in lesions that are otherwise indistinguishable from standard DFSP by histopathology. They have a slightly better prognosis than standard DFSP.

DFSP demonstrates a monotonous population of spindle cells arranged in a typical storiform pattern with bland-appearing tumour projections invading away from the major tumour, which can be difficult to identify histologically and presumably explains the high rate of local recurrence seen following limited excision margins. In most cases the diagnosis is straightforward with routine histology. Immunohistochemistry is useful to distinguish DFSP from other lesions but dermatofibroma, melanoma, leiomyoma and leiomyosarcoma and atypical fibroxanthoma cannot always be excluded. Over 85% of DFSPs label with CD34 but not factor XIIIa (labels the majority of dermatofibromas), vimentin or S-100, however DFSP with fibrosarcomatous transformation labels with CD34 in 50% of cases.

DFSP cells are characterized genetically by either a supernumerary chromosomal ring or linear translocation t(17:22)(q22;q13) in over 90% of cases. This alteration results in a fusion product involving platelet-derived growth factor B (PDGF-B) and the collagen 1A1 gene (*COL1A1*). This fusion protein leads to constitutive activation of the PDGF receptor resulting in cell growth.

The risk of distant or regional lymph node metastasis at presentation is very low, therefore preoperative imaging should be confined to evaluation of the primary tumour site by either MRI or CT scan. Planned margins of 2–4 cm usually result in tumour clearance and an acceptable rate of local recurrence (approximately 5% compared to rates >50% with incomplete/close margins).

DFSP with fibrosarcomatous change is reported to have a higher rate of local (38%) and distant (15% versus <5%) recurrence. In over 80% of cases involving fibrosarcomatous change, distant recurrence follows local recurrence, emphasizing the need for complete surgical excision.^{35,37} Even with wide margins of excision, recurrent lesions have a subsequently higher rate of local recurrence (11%).

Figure 11.5 (a) Recurrent dermatofibrosarcoma protuberans (DFSP) in a 44-year-old female. Typical pink thickened appearance seen in the initial stages. (b) Histopathology demonstrating cellular dermal and subcutaneous spindle cell proliferation with occasional storiform patterns (irregular whorl-like shapes) evident. Tumour is centred on the subcutis and appears to 'lift' subcutis into dermis. (c) Bland spindle cells wrap around and entrap subcutaneous lobules. Note the low-grade cytology.

DFSP is relatively radiosensitive but the role of adjuvant radiotherapy is currently undefined. In principle it should be reserved for cases where a complete excision is not possible or with extensive tumours. Specifically, patients with close margins should be managed by further excision if possible, rather than adjuvant radiotherapy. Targeted therapies to address the constitutive activation of PDGF-B in DFSP are currently being assessed. Initial reports of imatinib (a tyrosine kinase inhibitor that inhibits the PDGF receptor) for advanced or recurrent disease indicate a response rate approaching 50%. It may also have a preoperative role to improve tumour resectability.

Most recurrences occur within 3 years, however very late recurrences also occur. Follow-up by close physical examination and imaging of the primary site should be concentrated in the first 3 years. Ongoing annual follow-up after that time would seem reasonable.

Atypical fibroxanthoma

Atypical fibroxanthoma (AFX) is a rare and controversial tumour. Since first described over four decades ago, AFX is now recognized as a tumour of intermediate malignant potential that rarely metastasizes. It has considerable histological similarities to MFH, now classified as undifferentiated pleomorphic sarcoma (UPS). The majority of pathologists recognize both entities however at times it may be difficult to distinguish between them. UPS has significantly higher rates of local and distant recurrence and mandates more aggressive management. The risk of metastasis with AFX is very low (<5%) and some authorities argue that metastasizing AFX should be reclassified as UPS.

AFXs occur predominantly in the head and neck (80%) and/or sun-exposed areas of elderly males (median age 70). AFX of the limbs occurs in younger patients (median age 40). The histological appearances can be varied and the diagnosis is essentially

Figure 11.6 (a) Atypical fibroxanthoma (AFX) in a 65-year-old female. A raised pink lesion had grown slowly over at least 12 months. (b) Histopathology demonstrating a cellular dermal spindle cell tumour with attenuated overlying epidermis. (c) High-grade cytology with 'pushing' appearance and circumscribed deep border in deep dermis (not subcutis). (d) AFX usually appears as a high-grade spindle cell malignancy, with tumour giant cells and atypical mitoses that are out of proportion to low-grade clinical behavior.

one of exclusion. Immunohistochemistry may be of value in differentiating lesions such as melanoma or SCC (Figure 11.6).

Management is by wide excision (1 cm or greater) but there is no evidence on which to base margins. Local recurrence is uncommon (<10%) with adequate margins of excision and most recurrences occur in the first 2 years. Invasion beyond the dermis and local recurrence are associated with increased risk of both local and distant recurrence.³⁸

Cutaneous leiomyosarcoma

Leiomyosarcomas of skin are an uncommon group of tumours that can be further classified as superficial (cutaneous or dermal) or subcutaneous. The average age of onset is 40 with no gender bias. Over half present as innocuous, slow-growing nodules in the head and neck with the remainder in the extremities. Cutaneous leiomyosarcomata are relatively innocuous low-grade lesions and probably do not metastasize. Local recurrence is rare

following wide excision. Some suggest that they should not be regarded as malignant. Subcutaneous leiomyosarcoma has a higher rate of local recurrence and up to one third may metastasize.³⁹ There is little objective evidence on which to base surgical management. Margins of 2–5 cm have been reported but the critical issue is completeness of histological margins.

Cutaneous angiosarcoma

This is a heterogeneous condition that may develop in skin, the breast or in irradiated or chronically lymphoedematous tissue and in visceral sites. The most common (>75%) cutaneous site is the head and neck (particularly scalp). Most patients are male with a median age in the 70s. Most cutaneous angiosarcomas present as a small bruise becoming irregular, slightly raised with multifocal macules and papules that are purplish in colour (Figure 11.7). One third of patients have evidence of metastatic disease at presentation and work-up with

Figure 11.7 Typical appearance of an angiosarcoma developing in a 77-year-old woman. (a) The lesion is purple in colour and multifocal in appearance.

fine-cut CT chest and liver and whole-body PET scanning where available, is appropriate. Very wide excision is indicated, but angiosarcoma is frequently multifocal, leading to a high (50%) local recurrence rate despite clear margins. Wide-field adjuvant radiotherapy incorporating draining lymph node fields reduces the risk of local recurrence and anecdotal evidence suggests it may prolong survival.⁴⁰ The role of sentinel node biopsy is undefined. Most recurrences (local, regional and/or distant) occur within 2–3 years. The 10-year survival is approximately 20–30%.

Summary

The correct diagnosis and management of atypical tumours in clinical practice can be a daunting prospect. Revisions to tumour names, classifications and the emergence of mutational profiling has added to the challenge of managing patients with

these lesions. In general, atypical lesions are a testament to the potential for any cell or stem cell type to develop benign tumours or to undergo malignant transformation. Although the text is not exhaustive, we have sought to cover some of the more important and clinically relevant lesions. These are provided so that the clinician will have sufficient information so as to critically appraise any histopathology diagnosis provided and thereby ensure the appropriate management of their patient. More common tumours such as melanoma are capable of mimicry and therefore the diagnosis of melanoma or other common mimics should always be entertained when there is any discrepancy between the clinical picture and the results of histopathology. The appropriate management of malignant atypical lesions may require a dedicated multidisciplinary team within a tertiary or quaternary health centre. Careful consideration should be given to referring patients with atypical tumours that are at significant risk of recurrence and/or metastasis.

CHAPTER 12

Allotransplantation

Maria Siemionow¹ and Fatih Zor²

¹Department of Orthopaedics, University of Illinois at Chicago, Chicago, IL, USA

²Department of Plastic and Reconstructive Surgery, Gulhane Military Medical Academy, Ankara, Turkey

Historical background

Vascularized composite allotransplantation (VCA) involves transplantation of a vascularized graft, which is derived from different embryogenic origins and composed of a variety of heterogeneous antigenic tissues, across a genetic mismatch.¹

Trying to replace lost limbs and other organs is an old desire of humanity. The first historical mention of VCA dates back to Saints Cosmas and Damian (AD 286), who transferred an Ethiopian Moor's limb to a churchman.² Later, successful solid organ transplantations constituted the initial milestones of VCA. The first successful human allograft was performed in 1957 by E. Peacock. The allograft was composed of an en-block digital flexor tendon mechanism. However, this transplantation did not contain skin.³ In the 1960s, immunosuppression was limited, which led to the unfortunate rejection of the world's first hand transplant attempted by Robert Gilbert in 1964. Two weeks after the surgery, the graft was explanted and re-amputation was performed.¹ This complication delayed the next clinical hand transplantation, but studies about immunosuppression and experimental models continued to evolve to solve the problem. Once the clinical efficacy of cyclosporin (CsA) had been demonstrated in solid organ transplantation, studies began performing limb allograft transplantation in rats, dogs and rabbits. Hewitt reported the first successful rat limb allotransplantation in 1985.⁴ He also showed that transplanted bone marrow was functional and caused immune chimerism.⁵ During the same time period, Achauer mentioned the potential use of allografts for facial reconstruction in 1985.⁶ The first successful face transplantation in rats was performed by Siemionow and colleagues.⁷ Later, many models of VCA were developed and reported in both small and large animals.⁸ Pharmacologic research continued during this time and new drugs were developed for immunosuppression. In 2003, Siemionow reported the first and the only rat transplant model of life-long donor-specific tolerance using a 7-day protocol of anti-alpha/beta T-cell receptor monoclonal antibody and CsA.⁹

During the last 50 years, various clinical and experimental composite tissue allotransplantations have been performed, including: limb, trachea, flexor tendon apparatus, penis, nerve, knee, hand, face and abdominal wall.¹⁰

Nomenclature

An *autograft* is a tissue that is transplanted from one location to another in the same individual. When the graft is transplanted from a genetically identical donor, such as transplants between syngeneic animals and human monozygotic twins, it is called an *isograft*. An *allograft* is transplantation of tissues between genetically different individuals of the same species. *Xenograft* is transplantation between different species. Transplantation may also be described in terms of the site where the tissue is transplanted. *Orthotopic* transplantation means the recipient site is anatomically similar site and *heterotopic* transplantation means the recipient site is different from the site of origin.

Despite the encouraging results, debate continues over the immunosuppression-related risks. Thus, the ultimate goal of allotransplantation is to obtain *transplant tolerance*, which is rejection-free acceptance of transplanted organs or tissues without need for long-term immunosuppression. *Donor-specific tolerance* is defined as the state of donor-specific hyporesponsiveness in the recipient in the absence of immunosuppression. The state of tolerance to one organ or tissue (such as tendon) while simultaneously rejecting another (such as skin) is called *split tolerance*.¹¹ One of the best methods of obtaining tolerance is haematopoietic stem cell chimerism. In *chimerism*, tissues from two genetically different organisms coexist in one organism. There are two types of chimerism: *macrochimerism* and *microchimerism*. Macrochimerism occurs when bone marrow is transplanted to a conditioned patient, engrafted and produces all lineages. Microchimerism arises from the migration of donor leukocytes from the allograft to the recipient and in microchimerism donor haematopoietic stem cells do not engraft, but are produced and migrated systemically.^{12,13}

Basic transplantation immunology

The most important antigens contributing to allograft rejection are the major histocompatibility complex (MHC) antigens. The MHC proteins are encoded in chromosomes and have different nomenclature between species: HLA in humans, SLA in swine and RT1 in rat. There are two major classes of MHC antigens. Class I antigens are expressed on nearly all nucleated cells and serve as the primary target for cytotoxic (CD8+) T lymphocytes. Class II antigens are expressed primarily on vascular endothelium, antigen-presenting cells (APCs), B cells and activated T cells. Both class I and class II molecules have a specific site at which foreign peptide antigens can be presented after they have been processed by the cell. Following allotransplantation, foreign antigens are recognized by host T cells after being processed by host APCs. This is called indirect presentation. In addition, host cells can recognize donor MHC antigens, which is called direct presentation.¹⁴

The allograft rejection or allorecognition is primarily performed by T lymphocytes. The T-cell lineage marker is called TCR and there are two different types of T cells: $\alpha\beta$ T cells, which are responsible for the allograft rejection, and $\gamma\delta$ T cells, which are responsible for infections and antitumor activity. Mature $\alpha\beta$ T cells are subdivided into two groups: *T helpers* induce immune response and are CD4 positive, whereas *cytotoxic T cells* are responsible for cytotoxicity and are CD8 positive. Following allotransplantation, rejection begins with activation of T cells. The first step of T-cell activation is recognition of foreign antigen by T cells (signal 1). The second step is activation of co-stimulatory signals (signal 2). The third step is T-cell differentiation, which is performed by secretion of interleukin 2 following co-stimulatory signals (signal 3). Activated T cells are responsible for cell-mediated rejection of the allograft.¹⁵

The types of allograft rejection may occur and may be regulated by different mechanisms. Hyperacute rejection occurs within a few minutes after transplantation. This immune response is an antibody-mediated rejection process with the most frequent reason presensitized antibodies against MHC antigens. Acute allograft rejection is a cell-mediated immune response and is observed in all composite tissue allotransplantation cases. It is primarily attributed to T-cell activation. There is not enough information about antibody-mediated rejection (AMR) in VCA, but vascular rejection in solid organs is attributed to AMR. Chronic rejection is a common characteristic of solid organ transplantation; however there currently are insufficient data available to define the specific changes of chronic rejection in a VCA. It is characterized by fibrotic changes in the allograft, which may be caused by non-immunogenic factors.

In order to define and classify rejection, various classification systems have been developed. The most widely accepted classification system is the Banff Classification. In this system, the defining features used to diagnose acute skin rejection include: inflammatory cell infiltration with involvement of

epidermis and/or adnexal structures, epithelial apoptosis, dyskeratosis and necrosis. This classification system provides proposed schemas and represents the international consensus on this topic.^{15,16}

Transplant immunology is the most important area of research in VCA and many current studies are attempting to increase our knowledge of rejection mechanisms, routine immunosuppressive regimes, dosages and immune tolerance-inducing strategies. Today, the only method of graft rejection prevention is chronic immunosuppression. Unfortunately, there are several drugs and protocols, which are used experimentally and clinically. However, the ultimate goal of transplant immunology is to provide donor-specific tolerance.

The practice of immunosuppressive administration can currently be divided into three phases: induction, maintenance and rescue therapies. Induction immunotherapy is used as a means to overcome the ischaemic injury and surgical trauma an allograft undergoes during the transplant process. Maintenance therapy is defined as immune suppression that is typically much lower in dose than induction therapy and therefore applicable in a chronic setting. Rescue therapy is similar to induction therapy in that it employs high-dose immune suppression and is usually instigated in response to a rejection episode.¹⁵

Immunosuppressive therapy has well-documented side effects which may give rise to conditions that shorten life. The incidence and severity of such side effects are well described and this would allow an informed decision to be made as to whether these outweigh the potential benefit from VCA.

Experimental models of allotransplantation

Experimental VCA models help us to determine the technical feasibility of various immunosuppression and immune tolerance strategies and to evaluate their effects.

Animal models

During the last 20 years, many VCA models were developed for testing the feasibility of transplantation of different body components as well as for testing the effects of various immunosuppressive protocols. The experimental models can be divided into two main categories, namely small and large animal models, including non-human primate models. Another classification of experimental models depends on the type and content of the transplanted allograft:

- Skin-containing VCA models (groin flap, abdominal wall, etc.)
- Hindlimb allograft transplantation models
- Immunomodulatory VCA models (vascularized bone marrow, thymus)
- Facial allograft transplantation models (full face, hemiface, midface, etc.).

The basic experimental models and their specific features are summarized in Table 12.1.

Skin and soft tissue VCA models

These models include allografts containing skin, subcutaneous tissue, fat and muscle (Figure 12.1). The most frequently used skin-containing VCA model is the groin flap. This flap is also one of the first models used in allotransplantation research.¹⁷ This model contains skin, fat and lymphoid tissue harvested on superficial epigastric vessels or femoral vessels. The groin flap is frequently used in immunologic studies as it is technically simple and has low mortality. However, a disadvantage stems from the small size of the skin paddle. Other soft tissue flaps include both skin and various muscles such as the semimembranosus the pectoralis flaps.^{18,19} Another soft tissue model is the total abdominal wall transplantation, in which the entire abdominal wall skin is harvested on bilateral femoral vessels. This model was developed to investigate the effect of skin

amount on development of chimerism.²⁰ Figure 12.1 shows the skin and soft tissue models of VCA.

Hindlimb allotransplantation models

The rat hindlimb transplantation model was described in 1978.²¹ In this model, a circumferential skin incision at the mid-thigh level is made on the donor and superficial epigastric vessels, femoral vessels saphenous nerve and femoral nerve are dissected and thigh muscles are sharply divided. During muscle transection, the sciatic nerve is dissected. Next, the femoral bone is cut with a saw. The recipient is prepared using the same technique. Following division of the donor femoral vessels the limb is transferred to the recipient. First, the femoral bone is fixed with an intramedullary rod and wire suture. The femoral vessels are subsequently anastomosed and the femoral, sciatic and saphenous

Table 12.1 Experimental models of vascularized composite allotransplantation (VCA) and their specific features

	Experimental model	Tissues included, specific features
Skin-containing VCA models	Groin flap as vascularized skin transplant model	Skin, fat and lymphoid tissue. Simple, used in immunologic studies, small skin component
	Semimembranosus muscle and epigastric skin transplant model	Skin, fat, muscle and lymphoid tissue. Used for microcirculatory, physiologic and immunologic studies
Hindlimb models	Total abdominal wall transplant model	Skin, fat and lymphoid tissue. Contains large skin component
	Rat hindlimb transplant model	Popular, but technically challenging animal model containing all tissue components including vascularized bone marrow
Immunomodulatory VCA models	Groin–thigh osteomyocutaneous transplant model	Alternative model to hind limb transplant less challenging technique, low mortality
	Vascularized femur transplant model	Femoral bone, bone marrow, cartilage and muscle, applied for bone marrow-induced chimerism studies
	Bilateral vascularized femoral bone transplant model	Larger bone marrow content, applied for tolerance induction studies
	Composite vascularized skin/bone transplant model	Combination of groin flap with vascularized femur transplantation, enables follow-up of rejection
	Vascularized osteomyocutaneous iliac transplant model	Iliac bone, bone marrow, abdominal wall musculature and wide skin island
	Vascularized sternum transplant model	Sternum, skin and muscles. Contains bone marrow
	Thymus transplant model	Used for evaluation of effect of thymus on tolerance induction
	Osseomusculocutaneous sternum, ribs, thymus, pectoralis muscles and skin transplant	Includes all three important immunologic tissues (bone marrow, thymus and skin) for immunology and tolerance studies
	Full face/scalp transplant model	Includes ear, neck and facial skin without eyelids and nose; high mortality
	Hemiface/scalp transplant model	Unilateral ear, neck and facial skin. Used for immunologic studies in facial transplantation
Facial allograft models	Hemiface calvaria tarsnplant model	Temporal muscle and parietal bone included to hemiface scalp model. Contains bone marrow
	Hemiface mandible tongue allotransplantation model	Mandibular bone and tongue is included into hemiface model. Contains bone marrow
	Maxilla transplant model	Response of maxillary bone to transplantation
	Midface transplant model with sensory and motor units	First model to evaluate motor and sensory recovery after face transplantation
	Total osteocutaneous hemiface transplant model	Includes entire hemiface: vascularized nose, premaxilla, eyelids, upper and lower lips, external ear and facial skin for immunological, histological and biological evaluation of different facial tissues
	Composite face and eyeball transplant model	Evaluation of optic nerve regeneration and evaluation of orbit content

Figure 12.1 Skin-containing vascularized composite allotransplantation models. (a) Groin flap (*) raised on vascular pedicle (#) of the femoral artery and vein. (b) Semimembranosus muscle and epigastric skin flap model. * Indicates the epigastric flap, # indicates the vascular pedicle and 'smm' indicates the semimembranosus muscle. (c) Total abdominal wall transplant model harvested on the bilateral vascular pedicle of the femoral artery and vein.

nerves are coapted. Muscles and skin are closed anatomically. Hindlimb transplantation in the rat is a complex procedure involving connection of bone, muscles, nerves, vessels and skin. The rat hindlimb allograft transplant is the most popular animal model tested in preparation for human hand transplantation. This underlies the importance of having a fast, simple surgical procedure (with short anaesthesia) that provides good recovery for animals and consequently robust statistics.

In order to obtain a fast and simple limb allotransplantation method, Chang *et al.* described a groin–thigh osteomyocutaneous flap, which is composed of skin (groin), muscle (thigh) and bone (two thirds femur), based on the femoral vessels and superficial epigastric vessels.²² The advantages of this model are shortened operative time, easy monitoring of graft rejection, decreased morbidity and mortality rates, and capability for earlier postoperative ambulation.

Immunomodulatory VCA models

These models include vascularized bone and bone marrow transplantation and immunologic tissue transfers, such as thymus, in order to induce chimerism and immunotolerance (Figure 12.2). Vascularized femur transfer is composed of femoral bone, bone marrow, periosteum, cartilage and muscle tissues. This was initially described by Tai *et al.*²³ This model was used to investigate the effects of vascularized bone marrow transplantation on chimerism induction. A bilateral vascularized

femoral bone transplantation model was subsequently described by Agaoglu and Siemionow.²⁴ Bilateral femoral bones were harvested based upon the abdominal aorta and the inferior vena cava and after transfer connected to the same vessels in the recipient. This model included the same tissue types but with a larger bone marrow content, which was shown to induce higher levels of donor-specific chimerism in the recipient. Another vascularized bone marrow transplantation model was the composite vascularized skin/bone allograft model.²⁵ This model was basically a combination of groin flap with vascularized femur transplantation. The allograft was carrying both: the skin component to follow-up the rejection of the flap and bone marrow component to induce the chimerism. In order to reduce the morbidity and increase the allogenic load, a vascularized osteomyocutaneous iliac flap was described.²⁶ This flap included iliac bone, abdominal wall musculature and a wide skin island, harvested on iliolumbar artery and vein. It has a large skin island with bone marrow content, making this model almost an ideal composite tissue model. Unfortunately, it is a technically challenging model and, despite high bone marrow content, the chimerism levels were reported to be low.

Another bone marrow transplantation method is vascularized sternum transplantation. Sternum, including presternal skin and muscles, was first transplanted by Santiago *et al.*²⁷ The allograft was harvested on the thoracic aorta and superior vena cava.

Figure 12.2 Immunomodulatory vascularized composite allotransplantation models. (a) Vascularized femur transfer. * Indicates the femoral bone, # indicates the vascular pedicle of the allograft. (b) Bilateral vascularized femoral bone transplantation, * indicates the femoral bone, AO indicates abdominal aorta as the vascular pedicle of the allograft. (c) Composite vascularized skin/bone allograft model. * Indicates the femoral bone, # indicates the vascular pedicle of the allograft. (d) Vascularized osteomyocutaneous iliac flap. ** Indicates the iliac bone segment, # indicates the vascular pedicle of the allograft.

When the bone marrow-containing models are compared, it is seen that the limb model contains 48.75×10^6 bone marrow cells. On the other hand, iliac, femur and sternum models contain 25, 50 and 7.5×10^6 bone marrow cells, respectively. The results of these experimental studies also revealed that chimerism levels are directly related to the amount of bone marrow cells.

Another method of tolerance induction in experimental studies is to include thymus transplantation. The first thymus transplantation was described by Jiang *et al.* in 1999.²⁸ Later composite osseomusculocutaneous sternum, ribs, thymus, pectoralis muscles and skin allotransplantation model were developed.²⁹ This model includes three important immunological tissues (bone marrow, thymus and skin) and has the advantage of carrying marrow cells for chimerism induction, skin for monitoring of rejection as well as thymus for tolerance induction.

Facial allograft transplantation models

Because the face has many different anatomic structures and units, many facial allograft transplantation models have been developed to evaluate transplantation of facial structures (Figure 12.3). Siemionow *et al.* were the first to develop a full-face scalp allotransplantation model.³⁰ This facial allograft

transplant, which includes bilateral ear, neck and facial skin without eyelid and nose skin, is based on the bilateral common carotid artery and external jugular vein. However, because the operation was challenging, with a high rate of mortality, a hemiface scalp allotransplantation model was then developed in the Cleveland Clinic Laboratories.³¹ This model included scalp, the unilateral ear, neck and facial skin – excluding eyelid and nose skin – and was based on the unilateral common carotid artery and external jugular vein. The hemiface scalp allotransplantation model is generally used for immunologic studies about facial allograft transplantation. Yazici *et al.* developed a hemiface calvaria model by adding temporal muscle and parietal bone to the prior hemiface scalp model.³² This model included parietal bone with bone marrow cells, which were viable up to 100 days post transplant as confirmed by histology. The facial allograft model, containing mandible with bone marrow cells, was later described by Kulahci *et al.*³³ In this heterotopic allotransplantation model including hemiface mandible and tongue, Kulahci *et al.* showed high levels of donor-specific chimerism. In maxilla allotransplantation, the maxilla was dissected along Le Fort II osteotomy lines based on the common carotid artery and

Figure 12.3 Facial VCA models. (a) Hemiface and scalp allotransplantation model. (b) Hemiface mandible tongue allotransplantation model. (c) Midface transplant model with sensory and motor units. (d) Total osteocutaneous hemifacial allotransplantation model.

external jugular vein and transplanted. This model was developed to evaluate the maxillary response to allotransplantation.³⁴

The first model to evaluate motor and sensory recovery after facial allotransplantation was developed by Zor *et al.*³⁵ This composite midface transplant model with sensory and motor neuromuscular units included premaxilla, mystacial pad and nose with infraorbital and facial nerves. At 100 days post transplant, somatosensory-evoked potential (SSEP) and motor-evoked potential (MEP) tests revealed that sensory and motor recovery reached 67% of normal latency values for infraorbital nerve and 70% for facial nerve latency values. Recently, a total osteocutaneous hemifacial allotransplantation model was developed in order to extend the application of the face/scalp transplantation model in the rat.³⁶ This model included all hemifacial structures, such as vascularized nose, premaxilla, eyelids and upper and lower lips, external ear and facial skin. This new model, including all the hemifacial soft tissues as well as the premaxillary bone segment with nose components, enabled immunological, histological and biological evaluation of different facial tissues and structures in one complex composite allotransplantation scenario. The most recent advancement in facial allotransplantation models is the development of composite face and eyeball allotransplant model with optic nerve.³⁷ This experimental model provided evaluation of optic nerve regeneration and the effect of allotransplantation on composite facial tissues, including orbital content.

Large animal models and other VCA models

Other VCA models have been developed for the evaluation of posttransplant changes of various organs. Of these, perhaps the most important one is the cremaster muscle allotransplantation model, which was used to evaluate the microcirculatory changes following allotransplantation.³⁸ Laryngeal and penis allotransplantation models are other models that have been described.^{39,40}

Large animal models have also been developed for evaluation of feasibility and to encourage the clinical application of allotransplantation. Facial allotransplantation models have been described in various large animals such as dogs, rabbits and swine.⁴¹ A swine model of osteomyocutaneous radial forearm flap transplantation was described by Ren *et al.*⁴² Non-human primate models of face transplantation have been studied in cynomolgus monkeys.⁴³ Technical and immunosuppressive requirements for prolonged graft survival are studied in these models. Hand transplantation in non-human primates has been described in baboons and rhesus monkeys.⁴⁴ Both partial and total hand transplantation and immunology-related studies have been performed with these models.

Cadaver studies

Allotransplantation potentially solves challenging reconstructive problems by allowing the surgeon to place an entire *en-bloc* donor part (i.e. hand) onto a recipient. However, all technical aspects of harvesting and implanting this body part needed to be addressed by cadaveric studies. In terms of hand

transplantation, the anatomic and technical challenges have been determined already by experience with hand replantation cases. But facial composite tissue allotransplantation needed cadaver studies in order to determine time estimates, recommended sequence and type of dissection and pertinent anatomical structures. As a result, cadaver face transplantation studies are performed in preparation for clinical face transplantation.

The technical feasibility of face/scalp transplantation was first confirmed in cadaver studies by Siemionow *et al.*⁴⁵ Briefly, the whole face/scalp flap was elevated in the subplatysmal, sub-superficial musculoaponeurotic system (SMAS) and subgaleal

planes within the neck, face and scalp, respectively. In these studies, Siemionow *et al.* described the details of the surgical technique of face/scalp flap harvesting in a cadaver study (Figure 12.4).⁴⁵ They also demonstrated the integrity of the vascular territory following the flap harvest by methylene blue dye injection. As a continuation of this study, Siemionow *et al.* performed a mock transplantation by harvesting a total face/scalp flap in one group of cadavers and transferring the flap to the recipient cadavers.⁴⁶

During the donor flap inset, the anatomical consideration of the flap-anchoring sites and the length of arterial and venous pedicles and nerves incorporated in the flap were evaluated. The

vascular pedicle was found to be suitable for microvascular anastomoses, and nerve coaptation was possible. The mean total facial flap harvesting time was 235.62 ± 21.94 min. In this study, the sequence of procedures for mock facial transplantation was also described. Later, coronal-posterior approach for face/scalp flap harvesting from donor cadavers was developed to prepare extended length to the neurovascular bundles utilized in facial composite tissue allotransplantation.⁴⁷ It is suggested that the extended length of the neurovascular pedicle will not only provide easier vessel anastomoses and nerve coaptation but also provide the chance for meticulous haemostasis after artery and venous anastomoses.

Despite the continuity of its form and contour, the face can be surgically divided into distinct anatomic units. Each of these units is the object of a separate reconstruction. According to these anatomic principles, Lengele described three main segmental face transplantation types that can be harvested from one or more branches of the external carotid arterial network and includes certain sensory and/or motor nerves:⁴⁸ lower central facial allograft, midfacial allograft and upper facial allograft.

Lower central facial allograft (type I)

The lower central facial allograft includes the donor's nose, lips and chin, from the cutaneous surface to the deep mucosa. It is vascularized by bilateral facial vessels and contains all perioral muscles harvested under subperiosteal dissection. Motor innervations of these muscles arise from zygomatic, buccal and mandibular branches of the facial nerve, whereas sensory nerves including the mental (V3) and infraorbital (V2) nerves arise from the trigeminal nerve. If necessary, dissection can be extended deeper to include the middle part of the mandibular arch to restore bony support to the chin.⁴⁹

Midfacial allograft (type II)

The midfacial allograft contains the nose, upper lip, cheeks and muscles elevating the perioral structures. It is elevated equally on right and left facial pedicles. Although it can consist of soft tissues only, it may also include the anterior part of maxilla and zygomatic arches and variable parts of the anterior palate. Graft sensitivity is restored by infraorbital nerves (V2) with motor reinnervation relying on the zygomatic and buccal rami of the facial nerve.⁵⁰ Another midfacial allograft, Le Fort II-based osteocutaneous face transplantation, was described by Yazici *et al.*⁵¹ Using six cadavers, in combination with MRI and angiography, the authors showed the vascular territories in the masticatory space along with the internal maxillary artery's anterior pterygomaxillary extension.

Upper facial allograft (type III)

The upper facial allograft includes the superficial planes of the forehead, eyelids and root of the nose and the deeper planes of the frontalis, glabellar and orbicularis oculi muscles. It is elevated on the two superficial temporal pedicles and supraorbital

sensory nerves (V1). Motor innervation is provided by frontal and zygomatic branches of the facial nerve.

In addition to these three facial transplantation types, two more types are described by Lengele. According to Lengele, type IV is total face transplantation, which includes all three types, and type V is total face and scalp transplantation.⁴⁹

Face transplantation is potentially indicated only for defects that are not capable of reconstruction by conventional techniques and it is most appropriate that face transplantation be carried out only in patients with massive facial defects. Since these massive defects often include bone deficits, the indications for face transplantation may be more rewarding when bone and soft tissue replacement is needed.

Follmar *et al.* carried out mock osteocutaneous face transplantation in a cadaver model. The face was harvested in the subperiosteal plane and included the Le Fort III osseous segment. The allograft was inset by rigid internal fixation and soft tissue approximation. They showed that osteocutaneous face transplant procedure was technically feasible. On the basis of their experiment and review of prior investigations, the authors have identified 10 points that present technical challenges specific to osteocutaneous transplantation of the face. These included customization of the bony segment, sensory and motor innervation, extraocular movements, dentition, mastication, speech and swallowing, airway, vascular considerations, immunologic considerations and identity issues.⁵²

Baccarani *et al.* presented two face-harvesting techniques in a fresh human cadaver model. In first technique, the skin and soft tissue of the face was harvested by dissections in subgaleal, sub-SMAS and subplatysmal planes. In the second technique, the entire soft tissue and bony structures of the midface were harvested in a subperiosteal plane dissection combined with a Le Fort III osteotomy. Each face was harvested successfully as a bipedicle flap based on the external carotid arteries, the external jugular veins and the facial veins. The authors showed that each technique was a theoretically viable approach to face harvest for facial VCA.⁵³

Wang *et al.* compared two facial flap-harvesting techniques for alloplastic facial transplantation. They aimed to shorten donor graft harvesting time and reduce warm ischaemia. Six paired (SMAS) plane composite face/scalp flaps were harvested using either a superficial temporal artery (STA) or a facial artery (FA) pedicle technique or an external carotid artery (ECA) pedicle technique. They found that STA and FA pedicle flaps provide a shorter harvesting time and potentially safer dissection method for facial transplantation compared with previously reported total facial allograft harvesting techniques based on ECA pedicle.⁵⁴

Later Gordon *et al.* applied orthognathic principles and practice to maxillofacial allotransplantation. They planned the allotransplantation by either using dental cast models, cephalometric analyses, model surgery and occlusal splint fabrication or using a mimic Gunning splint (an edentulous scenario). It was shown that functional and aesthetic results are superior when using orthognathic principles.⁵⁵

More recently, Brown *et al.* incorporated computer-assisted planning and intraoperative navigation to improve precision and efficiency in complex maxillofacial allotransplantation procedures.⁵⁶ Ten mock facial transplantations including all facial skin, mimetic muscles, tongue, midface by means of a Le Fort III osteotomy and mandible by means of sagittal split osteotomies were performed. They showed that preoperative computer planning and intraoperative navigation provided precise osteotomies and a good donor–recipient skeletal match, which greatly reduced the need for intraoperative adjustments and manipulation.

Allotransplantation of the orbital globe and periorbital tissues was studied by Bozkurt *et al.*⁵⁷ In this cadaver model, they harvested the periorbital soft tissues, bony orbit and orbital contents by performing a box osteotomy. Both the ECA and the ophthalmic artery were prepared and indocyanin was used to show the perfusion of the flap.

Finally, cadaver studies have been performed to overcome some of the problems that have been confronted during the clinical application of face allotransplantation. The collected experience from prior facial allotransplantation has shown that the recovery of sensory function of the face graft is unpredictable. The most frequent problem in the clinical setting is the lack of healthy donor nerves, especially in central face defects. In their study, Rodriguez-Lorenzo *et al.* investigated the technical feasibility of transferring the supraorbital nerve to the infraorbital nerve in a model of central facial transplantation.⁵⁸ This study showed that supraorbital nerve to infraorbital nerve transfer is an anatomically feasible procedure in central facial allotransplantation and this procedure could be used to improve the restoration of midfacial sensation by the use of a healthy recipient nerve in cases where the recipient infraorbital nerves are not available.

Another nerve transfer study in allotransplantation was performed by Audolfsson *et al.* and evaluated the technical feasibility of performing nerve transfers in facial transplantation for both sensory and motor neurotization.⁵⁹ The first part of this study evaluated the technical feasibility of nerve transfer from the cervical plexus to the mental nerve and the masseter nerve to the buccal branches of the facial nerve. The second part aimed to simulate the face transplantation scenario, focusing on sensory restoration of the midface and upper lip by neurotization of the infraorbital nerve, sensory restoration of the lower lip by neurotization of the mental nerve, and smile reanimation by neurotization of the buccal branches of the facial nerve. The authors concluded that all nerve transfer procedures are technically feasible and could be used in face transplantation either as a primary nerve reconstruction, or as a secondary procedure for enhancement of functional outcomes.

Clinical applications of allotransplantation

VCA has considerable potential in reconstructive surgery. With proper immunosuppression and a very specialized surgical team, almost any missing part of the body can be restored using

principles of reconstructive transplantation. Many clinical VCA applications have been reported and the golden principles of every procedure are the same: proper selection of the recipient, a VCA well adapted to the needs of the recipient, correct immunosuppression and postoperative care. In this section, clinical applications of VCA are summarized.

Upper extremity transplantation

The loss of a hand or both hands is an important impediment for a patient and when replantation is impossible, the only solution remains hand transplantation. Since the first successful hand transplantation in Lyon in 1998, multiple hand transplants have been performed all over the world.^{60,61}

Because of the many years of experience with hand replantation, there are almost no anatomical and technical challenges regarding the procedure. The time estimates, recommended sequence of transplantation and pertinent anatomical structures are already known. Today, bilateral forearm amputation is the globally accepted indication for hand transplantation.

Patients with guillotine-type amputations at the level of the wrist joint and distal forearm are ideal candidates. In order to reduce the warm ischaemia time, two teams of surgeons working simultaneously are preferred. During the graft harvest, it is better to have more than enough length of all donor structures so they can be joined with recipient tissue without any tension. This is especially important for neurovascular structures. Both teams must use a tourniquet to operate in a bloodless field for optimal identification of all the available neurovascular structures, tendons and muscles. Extensive incisions in the forearm must be made for better exposure of the neurovascular structures for dissection. Incisions are not placed directly above nerves and vessels, as swelling may prevent direct closure, and the flaps must be prepared for Z-plasty transposition during closure. Skin incisions must be planned bearing in mind stump scarring and the possibility of creating a zigzag skin-flap closure.

Dissection and identification start at the subcutaneous level and continue down to the bone. All available structures must be tagged. After identification of all available structures, the tourniquet is released to control bleeding. When preparation of all structures of the donor hand is complete, it is perfused with 500 mL of chilled University of Wisconsin (UW) solution through the brachial artery. The sequence for hand transplantation is:

- 1 osteosynthesis;
- 2 vessel repair (anastomosis of the one main artery and two veins);
- 3 muscle–tendon repair/transfer;
- 4 definitive vessel repair;
- 5 nerve repair;
- 6 skin closure and dressing.

During definitive vessel repair, the two main arteries and at least 4–6 veins must be anastomosed. It is important to anastomose not only superficial veins but also deep vena comitantes. This is the guarantee for optimal venous return. All three main forearm/

hand nerves (median, ulnar and radial/superficial radial, depending on amputation level) must be repaired.

Following skin closure using the skin flaps in a Z-plasty manner, postoperative care and physical rehabilitation is started. The most important complications relating to hand transplantation are rejection episodes. Acute rejection episodes also have a negative effect on the outcome of upper extremity allotransplantation.

Immunosuppressive protocols for hand transplantation are similar to those for solid organ transplants and mainly include induction therapy with thymoglobulin or campath, combined with tacrolimus, mycophenolate mofetil and prednisone. Maintenance therapy usually consists of tacrolimus with mycophenolate mofetil and/or prednisone.

Face transplantation

The first successful face transplantation was performed on 27 November 2005 in France.⁴⁹ Since then there have been more than 27 reports of facial composite tissue allotransplantation.

Perhaps one of the most important issues in face transplantation is recipient selection. Today, the only scoring system developed for recipient selection is the Cleveland Clinic's FACES score.⁶²

Matching the donor and recipient is essential to ensure compatibility for the major (ABO) blood groups, as well as a negative cross-match between recipient and donor. Whether tissue matching for HLA poses a significant benefit on graft survival after facial transplantation is not known. Cytomegalovirus immunization status of the donor and the recipient must also be taken into account.

There are some screening issues unique to face transplantation. The transplanted tissue is visible, therefore must be cosmetically matched to the recipient. Broadly this means that the donor and recipient should be of the same sex and ethnicity and of similar age.

The surgery may begin simultaneously in donor and recipient but sometimes following the removal of all scar tissue, the actual defect of the recipient is determined and then the donor operation is started. The allograft is harvested based on a reliable pedicle, which generally includes either unilateral or bilateral facial and superficial temporal vessels. Depending on the reconstructive need, this allograft may contain soft and bony tissue and the level of the dissection may be sub-SMAS or subperiosteal. The motor and sensory nerves are also prepared. The steps can be summarized as: microvascular vessel anastomoses, fixation of the allograft, nerve coaptations, anatomical repair of muscles and other structures, and skin closure.

Physiotherapy and speech therapy (if indicated) may begin as early as 48 h following surgery. In general, rehabilitation consists of supervised controlled passive and active motion exercises, assessment of mastication, smell, speech, swallowing and facial expression. Gentle massage, sensory re-education, and facial acceptance education are encountered. Psychological status (i.e. anxiety, depression), quality of life and self-esteem of

the patient are evaluated. Sensory and motor re-innervations are closely monitored.

From an aesthetic standpoint, the patients are reported to be satisfied with their aesthetic result and have reported that they feel more comfortable in public even knowing that multiple surgical revisions such as scar revision and redundant tissue excision are necessary in order to obtain an optimal aesthetic outcome.

Other clinical VCA applications

Besides hand and face transplantation, there are other clinical applications of VCA, including larynx, trachea, knee, femur, abdominal wall, peripheral nerve, tongue, scalp/external ear, penis, uterus, flexor tendon apparatus, lower extremity and muscle.^{1,2,61} However, most of these applications are experimental, involving small numbers of cases.

Laryngotracheal transplantation

The first successful laryngotracheal allotransplantation was performed in Cleveland Clinic in 1988. The allograft included the entire larynx, and adjacent tracheopharyngeal structures including thyroid and parathyroid glands. Functional results and patient satisfaction was excellent, with normal swallowing and speech restoration. Later, more than 20 laryngotracheal transplantations were performed. One of these transplantations also included the oesophageal part; this was the first oesophagus transplantation.^{2,61}

Knee and femur transplantation

The first femur, knee and surrounding soft tissue transplantation was performed by Hoffmann in 1996. The initial results were good, but the long-term results were not satisfactory in most patients.^{1,61}

Abdominal wall transplantation

Abdominal wall allotransplantation was described by Levi *et al.* Abdominal wall composite allograft composed of both rectus abdominis muscles, overlying fascia, subcutaneous tissue and skin was harvested upon the inferior epigastric vessels. Abdominal wall transplantation patients received simultaneous intestinal or multivisceral transplantations without alteration of the immunosuppressive protocol required for organ transplants. Over 15 abdominal wall transplantations have been performed with satisfactory results.¹

Peripheral nerve transplantation

Mackinnon was the first to perform successful peripheral nerve allotransplantation. The immunosuppressive protocol of peripheral nerves differs from other transplantations. First, it is only necessary for 12–24 months and second it includes FK506, which is known to enhance nerve regeneration. The results of allogenic peripheral nerve transplantation were encouraging.^{2,61}

Outcomes

A total of 62 recipients have received either single or bilateral allotransplantation to date. According to the International Registry on Hand and Composite Tissue Transplantation (IRHCTT), acute complications of upper extremity transplantation are related to vascular surgery and are similar to free tissue transfers. There have been at least four cases of limb loss reported during the early (due to non-compliance) and late postoperative period. With a follow-up period of up to 15 years, it has been shown that immunosuppression-related complications include: serum sickness (3%), opportunistic infections (88%), acute rejection episode (85%) and metabolic complications,

such as hyperglycaemia, acute or chronic kidney disease, hypertension, Cushing syndrome and avascular hip necrosis (70%). Despite the immunosuppression-related complications, the functional outcomes of upper extremity transplantation are good. According to IRHCTT reports, 31 patients with at least 1-year follow-up have showed improvement in both the Hand Transplantation Scoring System (HTSS) and the Disabilities of the Arm, Shoulder, and Hand (DASH) score. It is reported that protective sensation, grip and pinch functions were provided in all patients.^{63,64}

Twenty-seven recipients have received partial or total face (cutaneous, myocutaneous and osteomyocutaneous) transplantation. Three of these died (one from infection, one from

Figure 12.5 Diagrams of the US first near-total face transplant, showing the sequence of the three-dimensional reconstruction that replaced 80% of the patient face. (a) The diagram of patient deformity following gunshot injury and conventional reconstructive operations. (b) Following debridement of all scar tissues, the full facial defect is shown. (c) The face allograft (back view and right anterior view), included 535 cm² of facial skin, functional units of full nose with nasal lining and bony skeleton, lower eyelids and upper lip; underlying muscles and bones including the orbital floor, zygoma, maxilla with teeth, hard palate and parotid glands, arteries, veins and nerves. (d) The diagram showing restoration of the patient's craniofacial defect after face transplantation.

stopping immunosuppression and the third from complications of long-term immunosuppression). In the clinical setting, all patients who received face transplantation accepted their new appearance without signs of psychological problems related to the transplantation.⁶⁵ Good functional and aesthetic results have been obtained. Dubernard *et al.* reported that sensory discrimination and hot–cold sensation returned nearly 18 months following the transplantation. Motor and olfaction functions also returned in face transplantation patients. However, in all reported cases, motor recovery was slower and less optimal compared to sensory recovery.

Siemionow *et al.* reported good functional outcomes for the first near-total face transplant (Figure 12.5).⁶⁵ The patient presented with return of breathing through the nose, being able to drink from a cup and eat solid foods. In addition, good sensory recovery was confirmed by restoration of sensation, which was close to normal. Motor recovery was also satisfactory, with return of essential facial functions such as pucker, smile and pronunciation of the vowels e, i and o.⁵⁰

All face transplant recipients with more than 1-year postoperative follow-up experienced at least one episode of acute graft rejection that was observed clinically and confirmed histologically on skin and mucosa biopsies.

Wound-healing problems, stenosis of Stensen's duct, postoperative ptosis and ectropion of eyelids were observed during the follow-up period and treated surgically. Despite standard antibacterial and antiviral prophylaxis protocols, the majority of recipients have experienced opportunistic bacterial, viral and fungal infections. Insulin-dependent new-onset diabetes mellitus, transient thrombocytosis, acute renal failure, thrombotic microangiopathy, transient steroid-induced confusion, transient leukopenia, posttransplantation monoclonal B cell lymphoma, cervical dysplasia, severe rhabdomyolysis, acute respiratory distress syndrome and diaphragmatic paralysis are the metabolic complications observed in face transplantation patients.^{63,64,66}

Future perspectives

VCA has been shown thus far to be a viable option in a particular subgroup of patients who suffer severe defects not amenable to modern-day reconstructive techniques. The long-term risks of current immunosuppression are the major concerns when debating this experimental surgery as improving 'only' quality of life. Thus, many experimental and clinical studies are currently focusing on newer immunosuppression options, such as donor-specific tolerance.

Transplantation of different structures is another topic of the future development for VCA. Experimental studies of an entire orbit, including the optic nerve, have already been performed and may allow clinical application in the near future. Research regarding transplantation of a whole head (allo-head and body reconstruction) has also begun to appear in the literature.⁶⁷

Although much of this may sound like science fiction, in the future, transplantation of the entire orbit for restoration of vision or transplantation cochlear apparatus for restoration of hearing function may become a clinical reality. We have to keep in mind that just a short time ago VCA procedures such as face transplantation were also considered to be science fiction.

CHAPTER 13

Radiation therapy and soft tissue response

Gurdip Kaur Azad and Carie Corner

Mount Vernon Cancer Centre, Northwood, UK

Radiation principles

Radiotherapy is the medical use of ionizing radiation, generally as part of cancer treatment to control or kill malignant cells. Ionizing radiation is composed of particles that individually carry enough kinetic energy to liberate an electron from an atom or molecule. Directly ionizing radiation consists of alpha and beta particles. Indirectly ionizing radiation includes photon radiation which may be gamma radiation if produced by radioactive decay or X-rays if produced outside the nucleus.

Alpha particle radiation

An alpha particle is identical to a helium nucleus, containing 2 protons and 2 neutrons. Alpha particles are generally produced by a process of alpha decay. If ingested, inhaled or absorbed into the bloodstream, they can cause severe damage. Radium-226, radon-222 and polonium-210 are alpha emitters. Most alpha emitters occur naturally in the environment and are found in various amounts in almost all rocks, soils and water. This form of radiation is rarely used for the treatment of cancer.

Beta particle radiation

Beta particles are high-energy, high-speed electrons or positrons emitted by certain types of radioactive nuclei. Cobalt-60, strontium-90 and iodine-131 are examples of some of the beta emitters. Iodine-131 is used in the treatment of benign and malignant thyroid disease. Strontium-90 is used in the treatment of metastatic bone cancer and has also been used for treating ocular melanoma. Beta particles are also a source of positrons used in positron emission tomography (PET).

Gamma radiation

Gamma rays are produced by nuclear gamma decay and are emitted from a radioactive source, often following the emission of a beta particle. Gamma rays are less ionizing but more penetrating than alpha and beta rays and can be stopped by a few centimetres of lead. The commonly used gamma emitters are caesium-137, cobalt-60 and technetium-99m. Technetium is

widely used for diagnostic studies, whereas caesium and cobalt are used in the treatment of cancer.

X-Rays

X-Rays, like gamma rays, are part of the electromagnetic spectrum. They are emitted by electrons. X-Rays of varying energies have many uses but are best known for their medical application. Low-energy X-rays (~10 keV) are used in diagnostic radiography to take images of part of a patient's body (e.g. chest or abdomen). The differential absorption of the X-rays by bone, air and soft tissue generates a clear radiograph. High-energy X-rays (photons) are able to ionize atoms and disrupt molecular bonds, thereby causing potential damage to the tissues they pass through. The ionizing capability of X-rays is utilized in radiotherapy, which uses photons to kill malignant cells in the treatment of cancer. In radiotherapy the photons are generated by a machine called a linear accelerator (linac). The linac generates electrons and then speeds them up to almost the speed of light using electrical fields. As the electron is accelerated its kinetic energy is increased until such time as it collides with the target and the energy is released as a photon (Bremsstrahlung radiation).

Mode of action in malignancies

When radiation interacts with cells, ionization of DNA molecules takes place causing tumour cell death. The biological effect of ionizations is controlled by a number of factors, such as the number of ionizations that can cause DNA damage, free radical scavenging processes and the degree of cellular repair. There are two mechanisms by which radiation causes cell damage: direct and indirect.

Indirect effect

Approximately 60% of the human body is made of water; therefore the majority of ionizations generated by irradiation arise in the water molecules. When radiation interacts with water it breaks the bonds that hold the water molecule together, producing

a positively charged hydrogen ion (H^+) and an uncharged hydroxyl radical ($OH^\cdot$). The OH radical is often called a free radical as it has an unpaired electron and is highly reactive, causing cell damage. These free radicals may undergo further reactions to produce hydrogen peroxide, which also contributes to the destruction of the cells. Oxygen plays a key role in this process of radiolysis. Approximately two thirds of the biological damage caused by X-rays or electrons is by indirect effect.

Direct effect

If radiation causes ionization of the atoms that are part of the DNA molecule, or some other cellular component essential for the survival of the cell, then the cell may be destroyed directly by interference with its life-sustaining structure. This is referred to as the direct effect of radiation.

Biological effect on the cell cycle

Cell cycle progression is vital for the growth and survival of a cell or organism (Figure 13.1). The normal cell proliferation cycle goes through two main phases, mitosis (M phase) and DNA synthesis (S phase), which are separated by the G₁ (before cell division) and G₂ (after cell division) phases. G₀ is the resting phase before cell division begins. The average length of a cell cycle is 16 h; this is shorter for cancer cells. Cell cycle arrest normally occurs in response to events that threaten the integrity of the DNA. Cells are most sensitive to radiation in the M and G₂ phases and most resistant in the S phase of the cell cycle. After radiotherapy is delivered, cells may be in different phases of the cell cycle. Fractionating radiotherapy may allow resistant cells time to enter the sensitive phase of the cycle and be more amenable to cell kill. Following radiotherapy, DNA damage can also cause a progressive delay in G₁, S and G₂ phases of the cell cycle. This delay gives the cells time to repair the damage.

Figure 13.1 The cell cycle. Radiation injury

Radiation kills actively dividing cancer cells efficiently; damage to cancer cells may occur immediately but may take months to take full effect. Along with the cancer cells, some rapidly dividing normal cells (skin, intestines, hair and bone marrow) are also damaged in the process, leading to unwanted acute effects. Slowly dividing normal cells (nerves, brain, bone, vessels) exhibit radiation-induced damage later.

Radiation-related injury to the cells is divided into three main categories:

- **Lethal damage** is a complex, irreparable and irreversible mechanism leading to cell death. The cell is unable to repair the damage and gives rise to a linear component of cell killing.
- **Sublethal damage** following ionizing radiation can be repaired within hours of the injury taking place and would not lead to cell death, unless further radiation exposure was inflicted on the cells. Cellular repair mechanisms can protect them from further injury, which is important for normal tissues, as they are able to repair themselves between fractions of radiotherapy. The approximate time needed for half the sublethal damage to be repaired (half-life) is different for different tissues. The recovery time is approximately 1 h and is thought to be complete by about 4 h in mammalian cells.
- **Potentially lethal damage** will inevitably kill the cells unless manipulated by repair-facilitated cell cycle arrest. Normal cells can readily be repaired in the S phase but not in the M phase. Tumour cells have defective cell cycle controls and therefore do not undergo cell cycle arrest required for repair, in contrast to the normal cells. A minimum of 6 h are required between fractions of radiotherapy to provide sufficient time for these repair mechanisms to work.

Modes of delivery

Radiotherapy delivered by a machine is often referred to as external beam radiotherapy. It may also be delivered by placing a radioactive source inside the body, which is referred to as brachytherapy.

External beam radiotherapy

This is the commonest form of radiotherapy used for the treatment of cancer. Different machines are used for the delivery of varying energies.

The superficial machine produces X-rays that range from 50 to 150 kV (kilovolts) and is used for treating superficial skin lesions. It deposits most of its energy at the surface of the skin and 90% of the dose at a depth of approximately 5 mm from the surface of the skin.

The orthovoltage machine generates X-rays ranging from 150 to 500 kV energy, depositing maximum energy near the surface of the skin and 90% of the dose at a depth of approximately 2 cm from the skin surface. It is also used for treating superficial tissues, skin and bone lesions.

The megavoltage machine produces X-rays of higher energies, usually 1 MV (megavolt) and above. A linear accelerator (linac) is commonly used for the delivery of these high-energy beams. The maximum dose of radiotherapy can be delivered to various depths depending on the energy of the beam used, aiding treatment of deep-seated tumours. Most linacs can also be adapted to treat superficial lesions, such as in cases of skin cancer. This treatment uses electrons instead of high-energy photons. Further technical advances in the design of the linac has permitted the use of intensity-modulated radiotherapy (IMRT) with the use of multileaf collimators (MLC). These are leaves of lead housed in the head of the linac machine, which shape the radiation beam according to the treatment volume and reduce the radiation dose to normal tissue.

Brachytherapy

Brachytherapy is a mode of delivering radiotherapy by using sealed radioactive sources which can be placed either inside a cavity containing the tumour (intracavitary) or directly in the tumour itself (interstitial). Other forms of brachytherapy include intraluminal, intraoperative, intravascular and surface brachytherapy.

The main radioactive sources used for brachytherapy are iridium, caesium and iodine.

The advantage of brachytherapy over external beam radiotherapy is the ability to deliver higher doses of radiation to the tumour and lower doses to the surrounding normal tissues. There tends to be a rapid fall-off in dose as the distance increases from the radioactive source, which restricts its use to the treatment of small and well-localized tumours.

Unsealed radioactive sources are also used for treatment and can be delivered either orally or intravenously. However, following treatment, limited-period precautions are necessary to avoid radiation exposure to individuals in close contact. Radioactive iodine-131 used in the treatment of thyroid cancer is an example of this form of treatment.

Fractionation

Curative treatment of cancer requires higher doses of radiation in order to produce sufficient cell killing. The total dose is delivered in small daily fractions over a period of time to minimize toxicity by allowing sufficient time for normal tissue recovery while inducing tumour cell kill. The efficacy of fractionation is based on the four Rs of radiobiology: repair of sublethal damage, redistribution of cells within the cell cycle, repopulation and reoxygenation.

By splitting radiation into small daily fractions, normal cells with efficient repair mechanisms are able to repair sublethal damage in contrast to cancer cells, which have suppressed repair pathways. Both normal and malignant cells repopulate between fractions. Prolonging total treatment time over several weeks allows normal cell repopulation, however some rapidly dividing tumours such as squamous cell carcinomas regenerate faster than the normal cells and exhibit accelerated repopulation. Fractionation increases damage to the tumour by allowing

reoxygenation of the tumour environment and redistribution of the cells into radiosensitive phases of the cell cycle.

Conventional (standard) fractionation is the delivery of 1.8–2 Gy per day, given as five daily treatments a week over several weeks. Other fractionating regimes used are as follows:

- *Hyperfractionation*: The same total dose is delivered over the same time as in standard fractionation but more than one fraction is given per day at a lower dose per fraction. This reduces the late effects of radiotherapy.
- *Accelerated treatment*: The total dose is delivered over a shorter period of time compared with standard fractionation in order to overcome accelerated tumour repopulation.
- *Continuous hyperfractionated accelerated radiation therapy (CHART)* combines the above two approaches and is used in the treatment of rapidly proliferating tumours (e.g. lung cancer and some head and neck malignancies). It consists of three smaller fractions of radiotherapy per day, separated by 6 h to allow recovery of normal tissues.
- *Hypofractionation*: Radiotherapy is delivered in a smaller number of fractions with a higher dose per fraction. There is potentially a higher risk of developing late effects in normal tissues with this regime. It is used in the treatment of slow-growing tumours which are generally resistant to standard fractionation schedules and also in the palliative setting where development of late effects are less relevant.

Dose and dose rate

Dose is the general term used to determine the quantity of radiation. The energy imparted by ionizing radiation to matter at a specific point is defined as absorbed dose. The SI unit of absorbed dose is joule per kilogram (J/kg) also known as gray (Gy).

Dose rate is defined as the radiation dose delivered per unit time and measured in grays per hour. Radiation response decreases with decreasing dose rate and this is referred to as dose rate effect. The typical dose rate used in standard radiotherapy is 1 Gy/min.

Effects of oxygen and radiotherapy

Malignant cells are most sensitive to radiotherapy in the presence of oxygen. Hypoxic cells are radioresistant and are usually present in the core of the tumour, whereas the cells on the surface of the tumour have an abundant blood supply and are well oxygenated. As the tumour is exposed to radiotherapy, the outer, well-oxygenated layers of the tumour are rapidly destroyed and the hypoxic inner layers become oxygenated and thus radiosensitive between treatment fractions.

Treatment parameters

Total dose

Total dose refers to the total amount of ionizing radiation absorbed by the patient (expressed in Gy). Every tissue in the body has a tolerance dose beyond which the organ would be

at risk of serious complications. Various dose/fractionation schedules can make it difficult to assess the total dose delivered to a particular organ. Therefore a formula is applied to compare altered fractionation doses to standard 2 Gy per fraction doses to know the exact total dose delivered to an organ. This is referred to as a biologically equivalent dose.

Dose fraction size

Fraction size is a significant factor influencing the development of acute and late effects of radiotherapy. Large fraction sizes increase the severity of late normal tissue damage.

Volume treated

The severity of acute and late normal tissue injury from radiotherapy depends on the volume of tissue irradiated. Tissues with a parallel organization, such as the lung and kidney, have a high functional reserve and exhibit a prominent volume effect. This means that the damage caused would depend on the dose distribution to the whole organ rather than to a small area. On the other hand, serial organs such as the spinal cord and gastrointestinal tract have little functional reserve and it is vital that radiation dose does not exceed tolerance at any point.

Time elapsed

If the overall treatment time is increased, a greater amount of repopulation of the irradiated normal and tumour cells is permitted. This has an adverse effect on local tumour control, especially in rapidly proliferating tumours.

Radiation effects

Acute toxicity

The acute effects of radiotherapy are generally defined as those toxicities occurring up to 90 days from completion of treatment. Acute effects usually manifest in rapidly dividing cells in the area being treated and are thought to be due to depletion of stem cells. Common sites exhibiting early radiation effects are the skin (including hair follicles and sweat glands), mucous membranes of the gastrointestinal tract and haematopoietic tissue.

If photon radiation is used it can take some weeks into the treatment course before erythema becomes evident, as initial dose is deposited in the deeper dermis. If a higher skin dose is required (e.g. when tumour involves the skin or in the treatment of a primary skin cancer), a tissue-equivalent bolus material may be applied over the treated field to increase the surface dose. Adjustments in radiation technique to use electrons or orthovoltage (less penetrating) radiation also increase the skin dose and result in the development of skin erythema within the first week of a fractionated course of radiotherapy.

The rates of onset of damage and recovery from it depend upon the turnover rate of epithelial cells. In a typical six-week course of radical radiotherapy delivered with curative intent one would expect skin erythema and inflammation to develop at the

treated site within the first three weeks. Epilation also occurs early and dry desquamation of the skin may follow as surface flaking of the stratum corneum. Towards the end of the course of radiotherapy moist desquamation of the skin is often seen, as exudate is released from the damaged skin cells. This is more commonly seen at the skin creases of the axillae and groins.

In radiotherapy to the head and neck, mucositis develops over the first few weeks, ranging from patchy isolated areas to confluent areas with ulceration. Taste disturbance is noted and salivary gland function is diminished. The latter results from acinar atrophy and chronic inflammation of the salivary glands.¹

Late toxicity

The late effects of radiotherapy are generally the dose-limiting factor. High total dose, large fraction sizes and large treatment volumes all contribute to a greater risk of late effects. The main mechanisms for the late effects of radiotherapy are believed to be damage to vascular and connective tissue and a reduction in the proliferative capacity of stem cells. Late effects tend to manifest in slowly proliferating tissues (e.g. lung, kidney, liver, heart and nervous tissue).

Late normal tissue damage reflects a failure to regenerate functional tissue, whether through lack of stem cells or radiation-induced dysregulation of the normal healing process. This latter phenomenon is described as a result of recent research into radiobiology and molecular pathology of late radiotherapy effects. Cytokine cascades are activated early at the cell and tissue level after irradiation and remain active throughout the expression of late tissue damage. Skin atrophy, telangiectasia, necrosis and fibrosis occur many months after radiotherapy. Skin atrophy is seen as shrinking and thinning of the skin in the irradiated field.² Telangiectasia results from a failure in the regrowth of normal vasculature. It has been postulated that telangiectasia results from loss of smooth muscle cells in vessels, leading to a loss of capillary pressure control. Loss of endothelial cells as a result of radiotherapy may also contribute to its formation.³ Necrosis is generally seen in atrophic skin often developing as a result of trauma, and reflecting the impaired reaction of the vasculature to tissue injury. Many late effects of radiotherapy can be attributed to fibrinogenesis and excessive extracellular matrix and collagen deposition. Increased knowledge of the relevant cytokines and their actions has provided molecular targets for potential therapeutic intervention.

Osteoradionecrosis

Osteoradionecrosis (ORN) can be defined as an area of exposed bone in a field of radiation that has failed to show any evidence of healing for six months.⁴ The incidence of ORN is believed to have declined considerably over time and reported incidence ranges from 3 to 5%.

The pathophysiology of ORN is described as a cumulative tissue damage induced by radiation. The three 'Hs' principle outlines how radiation results in a hypocellular, hypovascular and hypoxic tissue environment. Tissue breakdown occurs as a

result of cell death and collagen lysis exceeding cellular replication. The result is progression to a non-healing wound.

A key event in the progression of ORN is the activation and dysregulation of fibroblastic activity that leads to atrophic tissue within a previously irradiated area.⁵ High-dose radiation leads to bone death via a combination of mechanisms described as progressive resorption of osteoclasts, periosteocytic lysis, extensive demineralization and accelerated ageing of bone.

Common sites for bone necrosis are the jaw (soft tissue tumours of the head and neck), ribs and sternum (breast cancer), skull (brain tumours and soft tissue tumours of the scalp) and vertebral column (spinal cord tumours).

Factors contributing to the development of ORN include high radiation dose with the highest incidence occurring with radiation dose above 70 Gy.⁶ Large treatment volumes and high doses per fraction also impact on the probability of developing ORN.^{7,8} Poor dentition has been associated with a higher incidence of ORN of the mandible. Patients should have a thorough dental assessment and extraction of any teeth in poor condition prior to commencing a course of radiotherapy to the head and neck in order to optimize oral health. However ORN has been seen in edentulous patients also.

Advanced (stage III or IV) tumours/recurrent tumours, tumours invading bone, and tumours involving floor of mouth, tongue and retromolar trigone have been shown to have a higher risk of ORN.⁹

The presentation of ORN varies with site. In cases of ORN of the mandible patients may present with pain, swelling and trismus. ORN of the temporal bone can present with severe otalgia and offensive otorrhoea. Exposed bone and pathological fracture may also be seen. Imaging with plain radiographs may highlight areas of local decalcification or sclerosis. CT or MRI scanning is used to delineate the affected area prior to definitive surgery. A deep biopsy of the lesion to rule out recurrent malignancy is generally recommended.

Treatment of ORN involves initial measures such as control of any superadded infection, gentle irrigation of the soft tissues, nutritional support and analgesia. Hyperbaric oxygen therapy (HBOT) may also be considered.

Radiation therapy and wound healing

The wound-healing capacity of irradiated skin may be severely impaired. Clearly this has clinical implications for patients requiring surgery after radiotherapy. Approximately 60% of patients with solid malignant tumours receive radiotherapy as part of their treatment, either with curative or palliative intent. Radiotherapy is often used after surgery in malignant disease in cases of narrow or involved excision margins or to nodal basins post lymphadenectomy to reduce the risk of local disease relapse and improve overall survival. Radiotherapy may also be used before surgery to downstage a tumour prior to definitive resection (e.g. in preoperative radiotherapy for rectal cancer and head and neck cancer).

The process of wound healing is well described to occur in three phases: an inflammatory phase which develops within days, a proliferative phase which occurs over many days to weeks and a remodelling/maturation phase which extends from many weeks to years.

Unlike a surgical wound, however, fractionated radiotherapy results in repetitive injury to soft tissues. This results in an accumulation of inflammatory responses and dysregulation of this highly structured process of wound healing.

Cytokines known to be involved in the initial inflammatory response to tissue damage are transforming growth factor beta (TGF- β), vascular endothelial growth factor (VEGF), tumour necrosis factor alpha (TNF- α), interferon- γ (IFN- γ) and pro-inflammatory cytokines such as interleukin 1 and interleukin 8. These are all overexpressed following irradiation and lead to uncontrolled matrix accumulation and fibrosis.¹⁰

In the proliferative phase overexpression of additional cytokines (e.g. epidermal growth factor (EGF), fibroblast growth factor (FGF) and platelet-derived growth factor (PDGF)) leads to dysregulated granulation tissue formation, re-epithelialization and neovascularization.

Matrix metalloproteinases (MMPs) are responsible for the remodelling phase and regulate extracellular matrix synthesis. Irradiation can lead to dysregulation of MMPs leading to disorganized collagen deposition by fibroblasts.

There has been much interest in the postoperative complication rates of reconstructive surgery after radiotherapy and the optimal timing of surgery and radiotherapy. Much of the published literature is in reconstructive head and neck surgery and breast surgery.

It is understood that previously irradiated patients have a higher risk of postoperative complications.¹¹ In cases of microvascular free flap transfer TGF- β 1 has been shown to be overexpressed in free flaps for as long as six months after radiotherapy. Extracellular matrix remodelling has also been detected in the free flap for up to six months after radiotherapy completion.¹² The alteration in graft bed extracellular matrix organization after radiotherapy and prior to surgery has been shown to impact significantly on free flap survival in the pre-irradiated field.¹³

However several studies have been unable to demonstrate a significant difference in flap failure rate between irradiated and non-irradiated tissues. A large study by Bengston *et al.* used a prospective database to review 354 patients with a total of 368 free tissue transfers limited to the head and neck over a 4-year period. Postoperative complications in 167 patients who received preoperative radiotherapy were compared with 187 patients who did not undergo radiotherapy preoperatively. No significant differences in complications or flap loss between the two groups were noted. Total flap loss occurred in 5.3% in the irradiated group and 5.0% in the non-irradiated group. Major wound complications requiring additional surgery were seen in 16% of the radiotherapy group and 11% in the non-radiotherapy group. Interestingly, no significant difference in the timing or

dose of preoperative radiotherapy; previous neck dissection or anastomotic type was shown in failed versus successful flap.¹⁴

Similarly a smaller study of 100 patients undergoing fibular free flap reconstruction of the mandible retrospectively compared three groups: non-irradiated, preoperatively irradiated and postoperatively irradiated patients. Although 54% of patients experienced at least one postoperative complication, there were no differences among the three groups in the overall proportion of patients with complications of any severity: 54% versus 65% versus 46%. No case of complete flap loss occurred.¹⁵

It has been postulated that this failure of studies to show a significant difference in flap failure rates after preoperative radiotherapy in head and neck cancer may be due to a lack of statistical power owing to the very high success rate of microvascular free flap surgery.¹⁶

A recent small retrospective study of 12 previously irradiated patients with nasopharyngeal carcinoma who underwent salvage surgery and reconstruction from 2002 to 2007 found no intraoperative or significant postoperative complications. Four different types of flaps were used (two free and two pedicled) and all flaps survived.¹⁷

The timing of radiotherapy has been the subject of much debate with regards to the risk of delaying wound healing and reducing the success of microvascular free flaps when radiotherapy is used preoperatively. This has been retrospectively investigated for sarcoma patients where 119 patients with sarcomas of the head and neck; upper and lower extremities were reviewed with approximately two thirds receiving preoperative radiotherapy and one third receiving postoperative radiotherapy. Free flap loss rates were significantly lower in the preoperative radiotherapy group (0% versus 8.7%). Late recipient site complications also occurred less often in patients receiving preoperative radiotherapy (6.8%) compared to postoperative radiotherapy (26.1%).¹⁸

A review of 140 patients at the M.D. Anderson Cancer Centre who underwent mandibular resection and reconstruction with a free fibular flap compared preoperative radiotherapy and immediate reconstruction, preoperative radiotherapy and delayed reconstruction, postoperative radiotherapy and no radiotherapy. Complications included orocutaneous fistula, osteoradionecrosis and partial or complete flap loss. Forty-two per cent of all patients studied had at least one complication, but the incidence of complications was relatively equal between the groups receiving pre- and postoperative radiotherapy.¹⁹

Our practice in cases of preoperative radiotherapy for head and neck malignancies is to recommend surgery takes place within six weeks of completion of radiotherapy. Published data supports this approach showing an increase in flap loss, infections and delayed wound healing when more than six weeks elapses from the last radiotherapy session and surgery.²⁰

In breast cancer there has been much published literature on the optimal timing for breast reconstructive surgery in relation to receiving postmastectomy radiotherapy (PMRT). Baumann *et al.* studied 189 patients having delayed lower abdominal free

flap breast reconstruction. Eighty-two patients had surgery less than 12 months after PMRT and 107 had surgery 12 months or more after PMRT. The total flap loss rate was 2.6%, with all flap losses occurring in those receiving surgery within 12 months of PMRT. This group also trended towards a higher incidence of microvascular thrombosis, infection and wound dehiscence.²¹

However, a large metanalysis of 1105 patients found that delaying breast reconstruction until after PMRT had no significant effect on outcome.²²

Supportive management

Many of the early effects of radiotherapy are evident during a treatment course. Patients are given written advice on skin care management which includes the use of a daily emollient applied after each fraction of radiotherapy. Avoidance of direct sunlight on the treated area is imperative, as is avoiding the use of potentially irritating chemical containing compounds on the skin (e.g. body lotions, perfumes, talcum powders, etc.). If moist desquamation develops emollients are not helpful and paraffin gauze dressings may offer some comfort. Early detection and treatment of superadded skin infections with oral antimicrobials is recommended.

Oral mucositis often requires analgesia. Optimal pain control is essential to ensure patients are able to take adequate oral nutrition. Analgesia is given stepwise according to need using the World Health Organization (WHO) analgesic ladder. Analgesic mouthwashes can also be used. Early dietetic and speech and language assessment of these patients is important and if necessary parenteral feeding may be used if there is insufficient oral intake.

Xerostomia can be experienced early in the treatment course and is a well-documented late effect of radiotherapy after treatment of the salivary glands in head and neck malignancies. There are limited satisfactory treatment options to ameliorate this symptom. Artificial saliva sprays and gels may offer some relief. Due to the potential significant consequences of xerostomia on quality of life, which include increased rates of dental caries and oral candidiasis, and difficulty chewing and speaking, parotid-sparing radiation techniques are now used such as IMRT. Amifostine (a radioprotective agent) has also been shown to partially preserve parotid function after radiotherapy.²³

The management of late radionecrosis involves optimal wound care: adequate debriding and cleansing, accurately assessing the wound, choosing the appropriate dressing based on the wound assessment, and encouraging granulation tissue formation and re-epithelialization. Alginates, foams, gauzes, hydrogels, hydrocolloids and transparent films are the major moisture-retentive dressings available.²⁴

HBOT is frequently used to treat osteoradionecrosis and radionecrotic wounds. Standard wound care should also be followed.

The aim of HBOT is to reverse the radiation-induced hypocellular, hypovascular and hypoxic tissue environment. HBO consists of exposing a patient to intermittent short-term 100%

oxygen inhalation at a pressure greater than 1 atmosphere. HBO increases the oxygen concentration gradient so that the area around the necrosed hypoxic tissue has a high concentration of oxygen. This stimulates angiogenesis and reverses the hypoperfusion and hypoxia, giving tissues the propensity to heal. Initial reports of the benefit of HBO therapy were published as early as the 1970s. More recently a Cochrane Database Systematic Review of 11 trials concluded that for patients with late radiation tissue injury affecting the head, neck, anus and rectum HBOT is associated with improved outcome.²⁵

Early studies of pentoxifylline in combination with tocopherol have been shown to be efficacious in reversing radiation-induced fibrosis. Pentoxifylline may also have a role in the treatment of ORN. This oral drug has an anti-TNF effect and vasodilator action, which improves microcirculation and enhances oxygen delivery to tissues. Encouraging results have been shown in a small phase II study combining pentoxifylline with tocopherol (vitamin E) and clodronate for the treatment of ORN of the mandible, with all patients experiencing complete recovery within a median of nine months.²⁶

As the molecular basis of late radiation-induced tissue damage is now better understood, in particularly the specific cytokines central to the process, experimental molecular targets for therapeutic intervention are evolving. Injection of multipotent cells, topical administration of active substances to reduce the side effects of radiotherapy and the use of growth factors (e.g. TGF- β 1, 2 and 3), basic FGF, PDGF and VEGF are all areas for future development.¹⁰

Carcinogenesis

There is much evidence to support the carcinogenic property of ionizing radiation. Namely studies from atomic bomb survivors in Japan, the Chernobyl nuclear accident and people treated with high doses of radiation for cancer or other, benign conditions. In atomic bomb survivors the malignancies seen were leukaemias and carcinomas of cells that line the body. There was no increase in the incidence of sarcomas (soft tissue tumours) in these patients. The risk of developing a radiation-induced malignancy varied significantly with age, with young children found to be 15 times as sensitive as middle-aged adults.

A contrast is seen with second malignancies induced by radiotherapy. These cancers are of cells lining the body but are often seen in tissues or organs not directly targeted and that therefore have received lower doses of radiation. Sarcomas are noted to arise in high-dose areas of radiation that lie within or immediately adjacent to the radiation fields.²⁷

Up to 10% of invasive cancers are caused by radiation, both ionizing and non-ionizing radiation (ultraviolet, radiofrequency radiation). The probability of radiation causing a cancer is a stochastic effect, meaning the probability with which it occurs increases with effective radiation dose, but the severity of the cancer is independent of dose. The neoplastic transformation can be divided into three major independent stages: morphological changes to the cell, acquisition of cellular immortality

(losing normal, life-limiting cell regulatory processes), and adaptations that favour formation of a tumour.

Those cancers that may develop as a result of radiation exposure are indistinguishable from those that occur naturally or as a result of exposure to other carcinogens. The impact of lifestyle factors such as smoking, alcohol consumption and diet significantly contribute to many of the same malignancies. There is some evidence that these effects may not simply be additive but multiplicative.²⁸

A recent UK study estimated that 1346 cases of cancer, or about 0.45% of the 298 000 new cancers registered in the UK in 2007, were associated with radiotherapy for a previous cancer.²⁹ The largest numbers of radiotherapy-related second cancers were lung cancer (23.7% of the total), oesophageal cancer (13.3%) and female breast cancer (10.6%). The highest percentages of second cancers related to radiotherapy were among survivors of Hodgkin's disease and cancers of the oral cavity, pharynx and cervix uteri. Following initial radiotherapy for breast cancer, excess risks were seen for cancers of lung, oesophagus, bone and soft tissue.³⁰ Cancers most strongly linked to radiation include bone and soft tissue sarcomas, but skin, brain, thyroid, breast and stomach cancer can also occur (Figure 13.2). In most cases the risk of second malignancy is higher if the radiation exposure occurs earlier in life or during periods of rapid growth of a tissue, such as bone sarcomas during adolescence. Cells that have matured and are no longer proliferating appear to be less susceptible to the effects of radiation. Adolescent girls receiving mediastinal radiation therapy for Hodgkin's disease have been found to develop breast cancer more often than their adult counterparts.

Radiation-induced sarcoma

Radiation-induced soft tissue sarcoma is a rare malignancy with an overall incidence of less than 1% for patients with cancer who are treated with radiation and survive 5 years. Radiation-induced

Figure 13.2 An elderly woman who developed a biopsy-proven cutaneous squamous cell carcinoma within a radiation field given to her thyroid to treat a benign thyroid goitre 20 years earlier. Areas of fibrosis and telangiectasiae consistent with late radiation effects are also seen.

sarcoma has been defined as a lesion of different histology to that of a non-irradiated sarcoma, arising within a previous radiotherapy field, usually after a latency period of more than 4 years.³¹ Although the threshold dose for radiation-induced sarcoma is not certain, most published data report a dose of 40–60 Gy. Dose–response relationships have been found between radiation dose and sarcomas. A 40-fold increase in the risk of bone sarcomas was observed following 60 Gy or more.³² High-dose radiation appears not to increase the risk for leukaemia and thyroid cancer. Stereotactic radiosurgery data support that there may be a lower risk for induction of a secondary malignancy because of a very high probability of complete cellular kill in the high-dose radiation field. Cells lose their ability to proliferate and, therefore, they are unable to sustain a malignant transformation.

Although advances in the delivery of radiotherapy appear to reduce the risk of late radiation toxicity, the newer technologies, such as intensity-modulated radiation therapy (IMRT), involve the use of more fields and consequently expose more normal tissue to low-dose radiotherapy. To deliver a specific dose to the centre of the tumour, IMRT requires the accelerator to be energized longer, which results in higher radiation doses. Therefore, it has been estimated that the incidence of radiation-induced sarcoma may increase by 0.5% with IMRT.³³

Hereditary cancer syndromes

Genetic factors can predispose to a higher risk of developing radiation-induced second malignancy. About 5% of cancers are thought to arise in the context of a known hereditary cancer syndrome. Inherited gene mutations may lead to multiple tumours within the predisposed individual. Somatic cells may sustain transforming mutations following treatment with radiation and certain chemotherapeutic agents and lead to secondary cancers. Retinoblastoma and Li-Fraumeni syndrome are examples of such syndromes.

CHAPTER 14

Burns: acute care and reconstruction

Peter Dziewulski

St Andrews Centre for Plastic Surgery and Burns, Chelmsford, Essex, UK

Introduction

The skin is the largest organ in the human body, accounting for approximately 2 m² in an average adult. Burn injury to the skin can range from being trivial to one of the most severe insults that the human body can sustain. Every relatively small burn can have devastating lifelong functional and aesthetic sequelae. The aphorism 'a burn is for life' is true for the majority of burn patients.

Burns and their treatment have been depicted since prehistoric times, with cave paintings and subsequently writings by Hippocrates, Celsus and Galen. Ambrose Paré described burn wound excision and Dupuytren described six degrees of depth of burn injury that are still in use today. The twentieth century has brought great advances in burn care, including the scientific understanding of fluid loss and resuscitation, the hypermetabolic response to trauma, the control of infection and development of topical antimicrobial agents, the value of early burn wound excision and wound closure with autologous and allogeneic skin, cultured keratinocytes and the use of artificial skin substitutes.¹

Epidemiology

It is estimated that burn injury affects approximately 250 000 people in the United Kingdom per year. About 175 000 of these people attend emergency departments and 13 000 patients with burn injuries require admission. Approximately 1000 patients a year have burn of a severity to require formal fluid resuscitation. There are approximately 300 burn deaths per year in the UK.² The UK figures are representative of most of the developed world although the United States has a higher incidence, with approximately 1.4 million people sustaining a burn injury each year. Approximately 54 000–180 000 patients in the USA require inpatient care. Burns are a major problem in the developing world, with a much higher incidence and mortality, and

represent a significant burden of unmet healthcare need in many countries.³

About half of all admissions to burn units in the UK are children between the ages of 1 and 5 years and the incidence of injury in this age group remains static. The other vulnerable group are the elderly and the incidence of burns in this cohort of patients is increasing with increasing numbers of older people. The incidence of major burn injury in the developed world is on the decrease.

Most burn injuries are preventable. Prevention has traditionally been either via education or legislation. There have been numerous successful educational campaigns that have improved safety at home and in the workplace and that have also modified people's behaviour. Legislation has also been effective in prevention of burn injuries. Examples include sprinkler systems and smoke detectors in public and commercial buildings, fireguards, transport and storage of flammable materials and, more recently, controlling domestic water heaters.⁴

The burn team

The management of severe burn injuries requires integration of health professionals providing multidisciplinary care working to a common goal. The management of the complex nature of burn injury requires many different skills, which are usually not found in a single specialist. This means that comprehensive care of such patients involves a large team of professionals that includes plastic surgeons, intensive care specialists, anaesthetists, specialist nurses (burn, intensive care, children's), physiotherapists, occupational therapists, psychotherapists, psychologists, dieticians, pharmacists and social workers, all working together as the burn team. The multidisciplinary approach also involves collaboration between clinicians and basic scientists to establish a feedback loop of clinical and basic scientific inquiry. This care is best delivered in specialized burn units, where the multidisciplinary team of experts can all contribute to patient-centred evidence-based care.⁵

Burn classification

A burn can be defined as coagulative destruction of the surface layers of the body. Burn injuries can be classified according to their depth, aetiology and percentage body surface area involved. The combination of the above classifications allows quantification of the severity of the injury.

Depth

The skin is made up of the epidermis and dermis with the adnexal structures, such as the hair follicles, sweat and sebaceous glands residing in the deeper parts of the dermis. These adnexal structures are important as they are the source of proliferating epithelial cells (keratinocytes), which resurface wounds when the skin has been injured. Loss of the barrier function of the skin allows invasion of microorganisms and systemic sepsis. Increased fluid losses from the injured skin also occur until re-epithelialization occurs (Figure 14.1).

Burn injury to the skin can be classified as partial or full thickness. If the epidermis and the superficial part of the dermis have been injured (superficial partial-thickness injury), the majority of adnexal structures are preserved, epithelialization is rapid (10–14 days) and the risk of hypertrophic scarring is low. If the burn extends down into the deeper parts of the dermis more adnexal structures are destroyed, epithelialization is slower (3–6 weeks) and there is a high incidence of hypertrophic scarring.⁶ Full-thickness burns involve destruction all constituents of the skin and usually will require surgical intervention to achieve wound healing.

Aetiology

Burn injury can be thermal, electrical and chemical. Cold injury has a similar pathophysiology and radiation injury can also damage the skin.

Thermal injury

Thermal injury accounts for approximately 90% of all burns. The depth of thermal tissue injury is related to the temperature and duration of application.

Wet heat injuries such as scalds due to hot liquids are the commonest type of injury. They account for 70% of burns seen in children and are also common in the elderly. Scald injuries tend to cause partial-thickness injuries that will heal if treated conservatively.

Dry thermal injuries are typically caused by flame, direct contact or by radiant heat.

Flame burns are common in adults and are often associated with smoke inhalation injuries. They tend to be either deep partial thickness or full thickness and usually require surgical intervention. Radiant heat injuries are commonly sustained in house fires where patients are confined in a hot environment. Contact injuries occur by direct contact with a hot object. Prolonged contact with a moderately hot object such as a radiator can cause injury and is common in people who may have been unconscious or suffered a blackout for a period of time, such as the elderly, people with epilepsy, drug addicts and alcoholics. Contact burns tend to be deep and require surgical intervention.

Figure 14.1 Depth of burn wound. 1: Superficial partial-thickness burn – most adnexal structures intact. 2: Deep partial-thickness burn – only deep adnexal structures intact. 3: Full-thickness burn – all structures damaged.

Electrical injury

Electrical injury accounts for less than 5% of all injuries seen in a burns unit. They can be devastating irrespective of their size and can consume significant amounts of healthcare resources. They affect children and often working men and can have significant morbidity and long-term functional sequelae.

Injury severity is determined by voltage, current, type of current, duration of contact and path of current flow. The injury caused by electric current disrupts cell membranes to produce direct tissue damage. In addition it can also generate heat when passing through tissues that act as a conductor. In general, most tissues are good conductors, particularly nerves and vessels. These tend to suffer cell membrane disruption that leads to a progressive injury. Skin and bone are poor conductors although skin conduction does vary with humidity, temperature and sweating. The heat generated occurs around substances that are poor conductors, such as bone, which in turn damage the surrounding local tissues. Clinically there are often 'entry' and 'exit' points where the electric current has travelled from one point of the body to another.⁷

Electrical injuries can be subclassified into high- and low-voltage injuries, depending on the voltage of the electrical source.

Low-voltage injuries are those caused by <1000 V, such as those due to domestic electricity. They tend to occur indoors and cause small, deep contact burns at the points of entry and exit. The injuries tend to be localized. The alternating current can interfere with cardiac conduction and may lead to arrhythmias.

High-voltage injuries (greater than 1000 V) lead to extensive tissue damage and often to loss of limbs. Cardiac asystole and arrhythmias can occur. Muscle injury leads to rhabdomyolysis, compartment syndromes and renal failure. Fluid resuscitation is complex due to the 'hidden' nature of the injury. This type of injury has an associated high mortality.

Approximately 15% of such patients have an associated traumatic injury due to a fall from a height or being thrown. Compression fractures can occur due to tetanic muscle contraction following the electric shock.⁸

Flash injuries occur when current arcs from a high-voltage source. No current passes through the body but the heat from the arc can cause flash burns to exposed parts of the body (hands and face). The resultant burn is usually partial thickness unless the clothes ignite and give rise to a flame burn, which tends to be deeper.

ECG monitoring is required for all high-voltage injuries or if a low-voltage injury has given rise to cardiac arrest, an arrhythmia or a period of loss of consciousness. If an initial ECG is normal and there has been no history of loss of consciousness, cardiac monitoring is not required.⁹

Ocular sequelae are thought to occur in up to 20% of patients with electrical injury, although the exact pathophysiology remains unknown.¹⁰

Long-term neurological sequelae are common with both low- and high-voltage injury and can be very varied in their presentation, ranging from peripheral neuropathy to complex

neuropsychological problems and autonomic nervous system dysfunction.

The exact mechanism of neurological injury is as yet unexplained, but it is noted that resolution is better for early-onset lesions compared to late-onset ones.¹¹

Chemical injuries

Chemical injuries account for approximately 3% of patients seen in a burn unit. They mainly occur as household or industrial accidents. All chemical burns will involve the denaturation of proteins, and the severity of injury will depend on the concentration, quantity, duration of contact and mechanism of action of the chemical involved.

Mechanisms of action would include reduction, oxidation, corrosion, protoplasmic poisoning, vesication and desiccation. Although the exact mechanisms of tissue injury may be different, traditionally agents have been classified into acids or alkalis as the clinical pictures in each group are similar.

Acid burns produce damage by coagulative necrosis, causing precipitation of protein, which tends to be local and short lived. Alkali burns tend to cause progressive liquefactive necrosis, allowing deeper penetration and a prolonged effect. Cement burns are alkali burns, although they can also combine with sweat to produce an exothermic reaction. In addition, cement powder is very hygroscopic and will give rise to a desiccation injury.¹²

In principle, the management of chemical burns is the same whatever the agent involved. The area must be thoroughly irrigated with water after removal of any potentially contaminated clothing. Copious irrigation dilutes the chemical and limits tissue damage. This is usually performed by putting the patient in a shower (present in most emergency departments), allowing large volume and adequate drainage of the solution. Lavage for 30 min to 2 h may be required, although care must be taken to prevent hypothermia. There is no standardized measure of adequacy of lavage, although measuring the pH of the effluent can be helpful.¹³

Ocular injuries also require copious irrigation, followed by referral to an ophthalmologist.

For most chemicals there are no specific neutralizing agents and copious irrigation is the mainstay of initial care, although there are a few specific injuries where such agents are required.

Hydrofluoric acid is used widely for glass etching and in the electronics industry. It is very corrosive and toxic. The fluoride ion rapidly penetrates through the skin, causing progressive tissue damage and intense pain. It chelates calcium ions and can lead to hypocalcaemia, which can be fatal. After initial irrigation, calcium gluconate gel is applied topically to chelate the fluoride ions.¹⁴

Phosphorus has both civilian and military uses. White phosphorus ignites spontaneously in air and can be neutralized by immersion in or irrigation with water. Phosphorus particles can be removed from the wound and a solution of 0.5% copper sulfate applied, which turns the particle black to aid the identification and removal.¹⁵

Pathophysiology

Burn injury results in activation of an inflammatory cascade that can result in a local and a systemic response. Inflammatory mediators are released via the arachidonic acid pathway and activation of inflammatory cells. These mediators include histamine, prostaglandins (PGE₂), prostacyclins (PGI₂), leukotrienes, thromboxanes, kinins, serotonin, catecholamines, free O₂ radicals and platelet activating factor. Local action of these mediators includes endothelial gapping, increase in microvascular permeability and oedema formation. In addition, microvascular stasis and thrombosis can occur, which lead to progressive injury and cell death which produces clinical deepening of the burn wound.

Local effects

Zones of injury

The initial local effect of a burn injury can be divided histologically into three differential zones of tissue damage and blood flow:¹⁶

- *Zone of necrosis* – Central tissue necrosis due to destruction of tissue by thermal injury.
- *Zone of ischaemia* – A microvascular injury surrounding the zone of necrosis. The microvascular injury can be progressive and can lead to a clinical increase in burn wound depth.
- *Zone of inflammation (hyperaemia)* – Manifested by increased microvascular permeability that surrounds the zone of ischaemia.

Systemic effects

In burns involving over 20–30% of a patient's total body surface area (TBSA) the release of inflammatory mediators into the circulation will result in a systemic response. The systemic response is propagated by the inflammatory mediators described below, but in addition tumour necrosis factor alpha, interleukins 1, 6, 8, 12, 18 and interferon gamma have been implicated as mediators of a systemic response. The systemic effects are manifested in all organ systems and can lead to organ dysfunction and organ failure.¹⁷

The burn wound is thought to be the engine of the systemic response. Early aggressive wound excision and closure has been demonstrated to attenuate the systemic response.

Metabolic effects

Major burn injury involving over 40% of a patient's TBSA is associated with a hypermetabolic response characterized by an increased metabolic rate, muscle protein wasting, peripheral lipolysis, central fatty deposition, insulin resistance, immunosuppression, increased risk of infection and multiorgan dysfunction. It can persist for 1–2 years post burn and in children can reduce growth velocity. Such patients have increased resting energy expenditures, tachycardia and increased cardiac work with increased myocardial oxygen consumption. The peripheral lipolysis and central fatty deposition can lead to impaired liver function.¹⁷

The hypermetabolic response is mediated primarily by catecholamines and corticosteroids with a 10- to 50-fold increase of plasma catecholamine and corticosteroid levels that lasts up to nine months post injury. There are significant changes in homeostasis throughout systems mediated by a variety of other mediators and hormones. These include cytokines whose levels peak after injury and only approach normal levels at 3–6 months post burn. Larger TBSA injuries result in greater and more persistent inflammatory responses that are associated with increased cytokine levels and a greater hypermetabolic response.¹⁸

Serum hormone levels and acute phase proteins are all abnormal during hospital stay. Sex hormones and endogenous growth hormone levels are decreased, as are serum insulin-like growth factor 1 (IGF-1), IGF-binding protein 3 (IGFBP-3), parathyroid hormone and osteocalcin.¹⁷ Elevated levels of catecholamines, glucagon, cortisol and gluconeogenic hormones following burn injury lead to increased glucose production in the liver. Levels of insulin and fasting glucose are elevated and there is significant reduction in glucose clearance, leading to hyperglycaemia.

The resting metabolic rate of patients with burns >40% TBSA is twice normal levels. This reduces to 130% of normal level when the wounds are healed, but remains elevated for a long time, with levels being 110–120% at 12 months post injury.¹⁷

The hypermetabolism leads to muscle protein wasting, with loss of lean body mass, decreased strength and weakness that retards rehabilitation. Ten per cent loss of total body mass is associated with immunosuppression, 20% loss of total body mass with decreased wound healing and 40% loss of total body mass increases risk of death.¹⁹

Sepsis can increase resting energy expenditures and protein catabolism by up to 40% and due to post-burn immune dysfunction these patients are more susceptible to sepsis, leading to a vicious cycle of further muscle and protein catabolism and immune dysfunction.

Management

The management of a burn depends on accurate assessment of many variables. These include the age of the patient, comorbid factors and the size, depth and anatomical location of the injury. Once these have been assessed a treatment plan can be formulated.

In general, the aim of burn care is to restore form and physical and psychosocial function. This involves early aesthetic wound closure and optimal physical and psychosocial rehabilitation.

The vast majority of burns are small, do not need specialist care and can be managed on an outpatient basis. If there are concerns about safeguarding, patient reliability, follow-up or comorbidities then inpatient care should be considered.

Initial treatment consists of pain management, removal of clothing and debris, cooling the wound, cleaning the wound, tetanus prophylaxis and an appropriate dressing.

Cooling the wound with room-temperature or cool tap water provides pain relief and limits ongoing tissue injury. It is only effective for up to 30 min and excessive cooling can lead to hypothermia.²⁰

The management of burn blisters continues to be debated. In general, small blisters can be left, but larger ones should be deroofed and the fluid evacuated. Blister fluid content contains vasoactive compounds that can have a deleterious effect on the microvasculature. Aspiration of blisters increases the risk of infection.²¹

There are numerous types of dressings used in the management of these burns and some are described below.

Management of major burns

The immediate management of the major burn is conducted according to standard trauma or immediate care guidelines such as Advance Trauma Life Support (ATLS), Advanced Burn Life Support (ABLS) or Emergency Management of the Severe Burn (EMSB). These include assessment and stabilization of airway, breathing, circulation, disability, exposure and environment control. They also involve primary and secondary assessments for the depth and extent of the burn and an evaluation for associated life-threatening injuries are performed promptly upon admission (Table 14.1).

Table 14.1 Emergency management of burn injury

First aid	Stop the burning process Cool the burn wound
Primary survey	
A – Airway and cervical spine control	Clear airway Open airway – jaw thrust/chin lift Stabilize cervical spine
B – Breathing and ventilation	Expose chest and ensure equal and adequate expansion Ventilate or intubate if necessary ALWAYS PROVIDE SUPPLEMENTAL OXYGEN CO poisoning may give a cherry pink, non-breathing patient Beware respiratory rate >20/min Beware circumferential chest burns – consider escharotomy
C – Circulation with haemorrhage control	Check pulse Capillary refill test- >2 seconds abnormal check other limbs for hypovolaemia or need for escharotomy Stop bleeding with direct pressure Mental obtundation occurs with 50% loss total blood volume Pallor occurs with 30% loss total blood volume
D – Disability – neurological status	Establish level of consciousness A – Alert V – responds to vocal stimuli P – responds to painful stimuli U – unresponsive Examine pupillary response to light Hypoxaemia and shock gives a restless patient with decreased level of consciousness
E – Exposure + environmental control	Remove all clothing and jewellery Estimate burn surface area Keep patient warm
F – Fluid resuscitation proportional to burn size	Insert a large-bore IV line through unburned skin Take bloods – FBC/U&E/coagulation/ABGS/carboxyhaemoglobin Start fluids using modified Parkland formula: $\frac{1}{4}$ TBSA/kg/h for first 8 h (2–4 mL/kg/%TBSA: $\frac{1}{2}$ in first 8 h; rest in next 16 h) <i>from the time of injury</i> Add maintenance for children Warm Hartman's solution Replace blood losses with blood
Fluids	
Secondary survey	
History	AMPLE (Allergies, Medications, Past history, Last ate, Event)
Mechanism of injury	
Examination	Head to toe Urinary catheter
Monitor adequacy of resuscitation	Pulse, blood pressure, respiratory rate ECG, pulse oximetry, ABG Insert NG tube
Baseline investigations	
X-ray	Lateral C spine, CXR, pelvis
Pain relief	IV morphine titrated incrementally
Wound management	Cling film
Records	Re-evaluate Support and reassure patients, relatives and staff

Box 14.1 Referral criteria for specialized burn service.

- Consider if >3% TBSA partial-thickness burn
 - All burns association with electric shock
 - All burns association with chemical burn
 - All burns association with non-accidental injury
 - All burns to face, hands, perineum, feet
 - All burns circumferential to limbs or trunk or neck
 - All burns with inhalation injury
 - All burns not healed within two weeks.
- Discuss with local burn service:
- All burns with other injury
 - All burns with significant comorbidity or pregnancy
 - All infected burns
 - Any other case that causes concern.

Source: London and South East of England Burn Network Referral Guidelines. <http://www.lsebn.nhs.uk>

There are no universal definitions of severity, however a major or severe burn can be defined as the following:²²

- 25% TBSA or greater in the age group 10–40 years
- 20% TBSA or greater in children <10 years and adults >40 years of age
- 10% TBSA or greater full-thickness burns
- Burns involving eyes, ears, face, hands, feet, or perineum
- High-voltage electrical burns
- Burns complicated by major trauma or inhalation injury
- Burns in association with serious comorbidities.

Initial triage and care is usually provided within an emergency department and referral criteria can be useful for referral on to an appropriate burn service (see Box 14.1).

Burn wound assessment

Estimation of depth

Determining the depth of the burn wound can be difficult. The differentiation between superficial and deep partial-thickness injury is particularly important so that the clinician can predict if the wound will heal spontaneously within 14–21 days or will require excision and grafting to optimize healing and minimize scarring.²³ A false-positive assessment and the patient faces needless surgery; a false-negative one and the patient faces increased length of stay, risks contracture and hypertrophic scar formation.

Superficial partial-thickness wounds are pink, moist and blister. They blanch on pressure, are very painful and are fully sensate on pinprick testing. Deep partial-thickness burns will either be white or red with fixed staining. They do not blanch on pressure and have reduced sensation. Full-thickness burns characteristically have a leathery appearance and are insensate.

Diagnosing a very superficial burn or a full-thickness burn is usually accurate. Intermediate or deep partial-thickness burns can be more difficult to assess and are often indeterminate on first assessment. Accurate clinical diagnosis even by experienced

surgeons is possible only 64–76% of the time and is more inaccurate for inexperienced surgeons.²⁴

Many techniques have been described to aid diagnosis of burn depth, including surgery, biopsy, vital dyes, thermography, ultrasound and numerous other experimental modalities. The only technique currently routinely used in clinical practice is the laser Doppler, which can give an estimate of dermal blood flow and depth of burn injury. Laser Doppler scanning has been reported as predicting healing within 21 days in a number of independent studies in both adults and children, confirming a good correlation between the scans and clinical wound outcome and also predicting outcome ahead of clinical judgement.²⁵

It must be remembered that the burn wound is a dynamic entity and the depth can change over a 48 h period. No technique can accurately predict outcome from a single measurement so that repeated assessments are often required. It is reported that laser Doppler scanning is most accurate after the first 48 h.

Estimation of burn size

Accurate burn size estimation is key to assessment of the severity of the injury. Epidermal burns or erythema should be excluded and the size is estimated as a percentage of the patient's body surface area. It is recognized that initial assessment in the emergency department often overestimates the burn size by over 100%.²⁶ Other sources of error in the assessment include three-dimensional to two-dimensional translation and differences in patients' body mass indices (BMIs).²⁷

The simplest method of assessment uses the patient's hand as accounting for 1% of his or her TBSA, however this can lead to overestimation. The 'rule of nines' is useful for rapid estimation of size and can be converted to the rule of tens for children. In the rule of tens the head, anterior and posterior trunk all account for 20% TBSA, with the limbs each accounting for 10% TBSA.

The Lund and Browder chart (Figure 14.2) is the mainstay for assessment and documentation taking into account different age groups and their body proportions; however this technique has also been shown to overestimate burn size.²⁸ Recently the Lund and Browder chart has been incorporated into software for smart phones which can calculate the size of the injury from a drawing but also calculate fluid resuscitation requirements for the patient.²⁹

In addition using computer-aided 3D documentation systems, a 3D virtual body representation of the patient can be produced, aiding more accurate assessment and documentation. This software is also available for smart phones, aiding the clinician at the bedside.³⁰

Escharotomies

Escharotomy is required in circumferential full-thickness burns of chest, limbs or digits. Circumferential full-thickness burns in the limbs and/or digits act as a tourniquet, impair circulation, produce distal ischaemia and can lead to compartment syndromes, digital and limb loss. Circumferential full-thickness chest burns can restrict chest wall excursion and impair ventilation. Such burns require mid-axial escharotomies.

Figure 14.2 Lund and Browder chart. Source: Lund & Browder, 1944. The estimation of areas of burns. *Surgery, Gynecology and Obstetrics* 79:352–358. Reproduced with permission of Elsevier.

Escharotomies have traditionally been performed at the bedside but they are now undertaken in the admission room or operating theatre with an appropriate anaesthetic. The decision to perform escharotomy is a clinical one based on clinical appearance of the wound and the distal extremity. Assessment of distal perfusion includes skin temperature capillary refill, distal pulses (by palpation or Doppler ultrasound) and pulse oximetry. Pulse oximetry above 90% suggests adequate distal perfusion and no need for escharotomy.

The decision to perform chest escharotomy is usually based on signs of impaired mechanical ventilation, decreasing lung compliance, hypercarbia and respiratory acidosis.

A scalpel or electrocautery device can be used to incise through the full-thickness burn eschar down to bulging fat. The incisions should be placed in the mid-axial line and extend into adjacent non-burned or less deeply burned tissue. Since the wounds are full thickness, minimal analgesia or anaesthesia should be required, but extension into less damaged tissue can be very painful.

Complications of limb escharotomy include bleeding, arterial injury (brachial), venous injury (saphenous and cephalic), nerve

injury (ulnar nerve at the elbow, superficial peroneal nerve at the knee) and digital injury (neurovascular bundles and extensors).

Chest escharotomy can be a life-saving manoeuvre in the face of deterioration in ventilation. The escharotomy should be done on the anterior surfaces of the chest with incisions placed above and below the breast and along the anterior axillary lines. In children under the age of 2 years who utilize the diaphragm for ventilation and are 'belly breathers', the escharotomies should continue down onto the abdominal wall if it is also involved.

Compartment syndrome results from increased intracompartmental pressure. Fasciotomy must be considered in patients who have sustained high-voltage injuries, those with associated crush injury and those with very deep burns involving fascia and muscle. Carpal tunnel release should be considered as part of the same procedure in the upper limb. This phenomenon is discussed elsewhere in this book. Briefly, algorithms have been used for surgical decision making as to when to perform an escharotomy, fasciotomy or a carpal tunnel release. These are based on clinical signs and monitoring using the pulse oximeter and the Doppler flow meter.³¹ In addition, the use of compartment pressure monitoring either in the limb or intra-abdominally is a priority if there is any question about the diagnosis.

Smoke inhalation injury

Smoke inhalation injury is a serious associated injury that complicates cutaneous burn injury and carries a significant mortality risk.³² Smoke contains numerous noxious substances that are products of combustion, including soot, hydrocarbons, aldehydes, cyanides and carbon monoxide, which can produce both a chemical and asphyxiant injury.

Inhalation injury can be divided anatomically to upper airways injuries above the vocal cords (supraglottic) and those affecting the airways below the cords such as the trachea, bronchi and lung parenchyma (subglottic). The site of injury determines the diagnosis, management and outcome.³³

Upper airway injuries are usually thermal injuries to the mouth, oropharynx and larynx. Upper airway obstruction can rapidly occur due to oedema, making attention to the airway of paramount importance. These injuries usually resolve spontaneously as the oedema subsides after 3–5 days. These patients may require intubation and mechanical ventilation if the airway is at risk.

Lower airway and parenchymal injuries involve the trachea, bronchi and alveoli. They are thought to be mainly caused by chemical and particulate constituents of smoke. Some constituents of smoke, including carbon monoxide and/or hydrogen cyanide can impair oxygen delivery and extraction to and by the tissues.

The indications for endotracheal intubation include decreased level of consciousness airway obstruction and respiratory failure resulting from lower airway injury. Direct thermal injury to the upper airway can progress to complete airway obstruction within a matter of hours and intubation of such patients can be

very difficult or impossible. In this circumstance an emergency surgical airway or cricothyroidotomy should be considered. All burn patients with significant facial and airway oedema and those with inhalation injury should be assessed by a senior clinician with experience in managing difficult airways. It must be recognized that this group of patients may have a potentially difficult airway. Prophylactic intubation for transfer should also be considered where the airway is potentially at risk.

Lower airway injuries have always been thought to be chemical in nature, however thermal injury to the respiratory mucosa below the larynx involving the trachea and bronchi must occur when inhaling hot noxious gases. Inhalation injuries have a more prolonged course and are often associated with acute lung injury and pulmonary sepsis. The tracheobronchial mucociliary apparatus does not function, resulting in reduced clearance of particulate matter and cellular debris. These get trapped with a fibrinous exudate with formation mucous casts that can obstruct bronchi and smaller airways, leading to distal atelectasis, collapse and secondary infection. Direct alveolar injury can lead to impairment of gas exchange. Respiratory epithelial injury is usually self-limiting and recovers within about 14 days if there are no intervening complications.

Patients with smoke inhalation injury will often develop respiratory failure secondary to complex pathophysiological changes, including ventilation/perfusion mismatch, increased airway resistance, increased alveolar epithelial permeability, decreased pulmonary compliance and increased pulmonary vascular resistance. These changes give rise to impaired gas exchange, including hypoxia and hypercarbia that require mechanical ventilation. The positive pressure mechanical ventilation required following such respiratory failure will often result in increased airway pressures, shear/stress forces in the alveolus, giving rise to barotrauma and acute lung injury.

Carbon monoxide

Carbon monoxide is produced by the partial combustion of carbon-containing compounds and is a common cause of death at the scene in fires. It has a 300 times greater affinity than oxygen to bind to haemoglobin to form carboxyhaemoglobin, and can also directly impair mitochondrial function. Formation of carboxyhaemoglobin seriously impairs oxygen carriage and delivery in the blood. The organs most vulnerable to carbon monoxide poisoning are therefore the cardiovascular system and the brain. Symptoms include headache, nausea and malaise. Cardiac problems include tachycardia, hypotension and arrhythmias. Central nervous system symptoms can include delirium, seizures, unconsciousness, respiratory arrest and death.

Diagnosis can be made by direct measurement of carboxyhaemoglobin levels and measuring the arterial saturation of oxygen analysed using a co-oximeter. Standard pulse oximeter measurement of oxygen saturation provides a falsely high peripheral saturation reading, even with lethal levels of carboxyhaemoglobin, because the oximeter is unable to distinguish between carboxy and oxygenated haemoglobin.³⁴

Carboxyhaemoglobin has an elimination half-life of 4 h on room air but on inspiration of 100% oxygen, via a non-rebreathing mask, this drops to 30 min. The mainstay of management of carbon monoxide poisoning is high-flow (100%) oxygen therapy.

Hyperbaric oxygen therapy improves the clearance of carbon monoxide compared to 100% oxygen therapy and some authors have recommended its use for prevention of delayed neurocognitive syndrome. However, on review of the evidence, the Cochrane group have concluded that hyperbaric oxygen for this indication has not been shown to have any benefit and in particular there is no evidence of benefit in the patient with a cutaneous burn, smoke inhalation and carbon monoxide poisoning.³⁵

Cyanide

Hydrogen cyanide is a cellular poison that binds to the terminal cytochrome on the electron transport chain, inhibiting cytochrome *c* oxidase and making the cell unable to utilize oxygen. This can cause a profound lactic acidosis, accompanied by elevated mixed venous oxygen saturation. Cyanide is produced by the combustion of plastics, paints, wool and silk.

The half-life of cyanide is about 1 h and can be associated with a significant number of smoke inhalation injuries and carbon monoxide poisoning. Signs and symptoms are often similar to those of carbon monoxide poisoning, including central nervous and cardiovascular effects. Burn patients will typically have a metabolic acidosis that is out of keeping with the size of burn and clinical picture. A rapid assay is not available, making diagnosis difficult. A simple aid to diagnosis is an arterio-venous oxygen saturation difference of less than 10%, measured by taking arterial and venous blood gas samples. This indicates an inability of the tissues to extract oxygen from the blood.

Hydroxycobalamin (a form of vitamin B12) is the antidote treatment of choice, rapidly chelating cyanide to form cyanocobalamin. It is safe and rapidly effective but multiple doses are often needed.³⁶ In some healthcare systems it is given to all patients involved in house fires with signs and symptoms of a smoke inhalation injury.

Sodium nitrite and sodium thiosulfate have been used in the past but nitrites produce methaemoglobin, which, although it chelates HCN, also reduces oxygen carriage in the blood and can cause profound hypotension. Sodium thiosulfate, which binds to cyanide and is excreted in the urine, is safer but its action is slow.³⁷

Diagnosis of smoke inhalation

Diagnosis of inhalation injury is mainly clinical. The mechanism of injury, signs, symptoms and physical examination are important in raising suspicion of the diagnosis but are not absolute. Signs and symptoms of an upper airway injury include facial burns, facial swelling, burned nasal hairs, soot in the nose or mouth, intraoral swelling, oedema visible on laryngoscopy, hoarseness of voice and stridor. Lower airway injuries are

suggested by a history of a fire in an enclosed space, loss of consciousness, obtundation, anxiety, facial or intraoral burns, soot in the mouth or nostrils, cough, dyspnoea, wheeze, carbonaceous sputum and signs and symptoms of respiratory distress such as tachypnoea, use of accessory muscles of respiration, cyanosis and impaired gas exchange.³⁸

Patients who have a history of injury in a closed space, facial burns, large burn sizes or advanced age are more likely to have smoke inhalation injury. Investigations such as chest X-ray and arterial blood gases are often initially normal. Later changes evident on the chest X-ray include bronchial thickening, perivascular cuffing, interstitial pulmonary oedema, atelectasis and consolidation. Carboxyhaemoglobin levels are useful, although normal levels do not exclude smoke inhalation injury.

Fibreoptic bronchoscopy is the 'gold standard' for the diagnosis. Grading systems are available for the severity of injury, however in general they are not prognostic.³⁹ False-negative results can occur early on following admission, especially if the patients are hypotensive, so a repeat bronchoscopy is usually performed 48 h after admission. Recently, authors have reported the successful use of CT scanning within a few hours of injury. This is said to be predictive of outcome in terms of duration of ventilation and intensive care stay.⁴⁰

Xenon-133, a radioactive tracer, has been used to visualize small airway injuries and aerosolized technetium 99-m complexed to diethylenetriaminepentaacetate (Tc^{99m} -DPTA) has been used to assess the alveolar capillary membrane. Both techniques are only used for research and not on a regular clinical basis.

Management of smoke inhalation injury

Fluid resuscitation of patients who have smoke inhalation injury associated with a major burn can be very challenging. Such patients have significantly greater fluid resuscitation requirements during the first 48 h post burn.⁴¹ Unfortunately, more fluid administration leads to problems associated with excessive fluids, including compartment syndromes and pulmonary oedema. Conversely, there is no evidence that fluid restriction protects the lungs or improves outcome. Strict attention to fluid administration and balance must be paid to these patients during the resuscitation period.

Pharmacological management with inhaled heparin, acetyl cysteine and salbutamol can be used to limit the duration and incidence of cast formation and mucous plugging of the airways. Heparin inhibits fibrin plug formation,⁴² acetyl cysteine is a mucolytic and salbutamol a beta-adrenergic agonist. Retrospective analyses of case series have demonstrated a benefit in children⁴³ but not in adults, possibly highlighting the difference in both anatomy and physiology between children and adults.⁴⁴

Mechanical ventilation is the treatment of respiratory failure and not the treatment of smoke inhalation injury. Patients who have upper airway compromise or impaired gas exchange may require mechanical ventilation. The optimal mode of mechanical ventilation for such patients is yet to be determined.

Conventional ventilation with lower tidal volumes (5–8 mL/kg) and permissive hypercapnia have been shown to improve survival in patients who have acute respiratory distress syndrome and burns under 30% TBSA. Mechanical ventilation for burn patients who have sustained smoke inhalation injury should focus on providing pulmonary toilet, improving alveolar recruitment, reducing alveolar shear/stress and avoiding ventilator-induced lung injury.

High-frequency ventilation is commonly used in the management of smoke inhalation injury, however there is currently little direct clinical evidence of outcome benefit of using either an oscillatory ventilator or a volumetric diffusive respiration ventilator in such patients.³³

Tracheostomy

The role of tracheostomy in patients who have smoke inhalation and cutaneous burn injury remains debated. The route of intubation seems less important than the avoidance of high peak inspiratory pressures and high cuff pressures.

Recent studies in burn patients have demonstrated no difference in outcome related to the timing of insertion or technique used for insertion (open/percutaneous) of a tracheostomy. Prolonged endotracheal intubation prior to tracheostomy seemed to be a risk factor for swallowing problems and subglottic tracheal stenosis following tracheostomy.

In general, early tracheostomy should be considered for patients with extensive full-thickness facial and neck burns and those who are predicted to require a long duration of respiratory support. Tracheostomy should also be considered at about day 14 post injury in patients who are still slow to wean or who have failed attempts at extubation.⁴⁵

Fluid resuscitation

Burn injury produces both local and systemic effects, giving rise to loss of capillary integrity with leakage of fluid and protein from the intravascular to the interstitial space with the formation of oedema. In addition, intracellular oedema can occur following a drop in the transmembrane electrical potential of cells, giving rise to an increased intracellular sodium concentration caused by a postulated circulating shock factor. In burn size of 25% TBSA or more the oedema is generalized and occurs in non-burned tissues such as the gut, lung, muscle, heart and brain. The amount of oedema in all tissues is directly proportional to the burn size. In major burn injury this fluid loss can lead to hypovolaemia and shock and therefore fluid resuscitation is critical to the survival of such patients.⁴⁶

The increase in capillary permeability is transient and occurs in the first few hours following injury, caused by the systemic inflammatory mediators. The capillary leak usually resolves within a few hours to days, however in some patients it can be prolonged. Oedema continues to develop for at least 24–36 h post injury due to loss of plasma colloid osmotic pressure and

resultant decrease in the colloid osmotic pressure gradient. Correction of the hypoproteinaemia with infusions of albumin or plasma is thought to promote and prolong the development of oedema.⁴⁶

Burn shock is characterized by specific physiological changes that include an initial decrease in plasma volume and cardiac output, producing oliguria. A 'myocardial depressant factor' or inflammatory mediators have a role in the immediate fall in cardiac output observed in large burns.

The primary goal in resuscitation is to restore circulating blood volume and to preserve tissue perfusion and oxygenation. Greater volumes of fluid used in burn resuscitation lead to greater oedema and increases in weight of up to 20%. Significant oedema is characteristic of large burn injuries and is paradoxically aggravated by fluid resuscitation itself. Excessive fluid administration can give rise to 'fluid creep' and compartment syndromes.⁴⁷ Monitoring and constant re-evaluation of the resuscitation process are essential to success. The formulas are only guides and can be unreliable in the young, old, in larger burn injuries, in patients with other injuries or concomitant medical problems.

In principle, to achieve survival, patients with extensive burns need to be given large quantities of fluid, which must contain sodium salts. The total volume of salt-containing fluid required to satisfy obligatory burn oedema and make good urine losses is between 2 and 4 mL/kg/% burn. The actual volume is dependent upon the type of salt solution used. The quantity of sodium ions required for effective resuscitation is of the order of 0.5 mmol/kg/% burn. The resuscitation fluid should preferably be a balanced salt solution with chloride content not exceeding 100 mmol/L and with bicarbonate and/or lactate as the secondary anion. The total water requirement (and sodium concentration of the resuscitation fluid) varies depending on the treatment of the burn wound. The amount of sodium-free water given should be minimized to that required to prevent hypernatraemia.⁴⁸

Burns greater than 15% of the TBSA in an adult and 10% in a child have traditionally been thought to require formal fluid resuscitation; however, large burns are commonly resuscitated in the developing world with oral rehydration using Dioralyte or Moyer's solution (4 g NaCl plus 1.5 g NaHCO₃ per litre of water). In the developed world this would only be recommended in exceptional circumstances, however in the future this may be a way of avoiding excessive fluid administration.

The optimal fluid and formula for resuscitation is still debated and the value of colloid is still unclear. Fluid resuscitation is a dynamic process and all formulas are only guidelines. Constant monitoring of the patient, re-evaluation of progress and adjustment of infusion volumes are the key to success.

The choice of formula depends on local circumstances, experience and expertise. A formula should be easy to understand and regular use will lead to familiarity and confidence. Commonly used resuscitation formulas are given in Table 14.2.

The Parkland formula is commonly used to calculate fluids for the first 24 h (2–4 mL of Ringer's lactate or Hartmann's

Table 14.2 Formulas for fluid resuscitation and ongoing metabolic requirements

Crystalloid resuscitation: Parkland formula	
Adults	2–4 mL × weight (kg) × burn % TBSA = volume given in 1st 24 hours (equates to 0.25 mL/kg/%TBSA/h in 1st 8 h) Using Hartmann's solution or Ringers lactate ½ given in first 8 h, remainder in subsequent 16 h Includes metabolic requirement in adults
Children	As above but add maintenance requirements as dextrose saline or feed 4 mL/kg/h for 1st 10 kg 2 mL/kg/h for 2nd 10 kg 1 mL/kg/h for 3rd 10 kg
Ongoing fluid requirements (after 24 h)	
Adults	1500 mL/m ² BSA (maintenance) + 3000 mL/m ² burn BSA (burn losses) per 24 h
Children	1500 mL/m ² BSA (maintenance) + 3750 mL/m ² burn BSA (burn losses) per 24 h

solution per kilogram body weight per percent TBSA burn with half the volume given in the first 8 h post burn). Resuscitation should use the least amount of fluid required to achieve adequate urine output and other physiological endpoints. Recent concerns about fluid creep have instigated further ongoing debate about fluid resuscitation.⁴⁹

The volume and constitution of fluid therapy in the second 24 h period remain debated, with the use of colloid regaining popularity. Colloid requirements of 0.3 and 0.5 mL/kg/% TBSA burn have been suggested to re-expand the plasma volume following resolution of the capillary leak in most but not all patients.⁵⁰

The concerns about the loss of capillary membrane integrity and leakage of infused proteins into the interstitial space, especially in the lung, has led to the avoidance of colloids in the first 24 h post burn. Some authors argue for maintenance of intravascular volume by the use of early albumin infusion and others advocate an intermediate approach, giving colloids at 8–12 h post injury after capillary leak has resolved.⁵¹

Colloid has traditionally been administered as 5% albumin, however the use of other non-protein colloid solutions, such as dextran, pentastarch or hetastarch, in burn resuscitation has also been described. Recently, concerns about hetastarches have led to their disuse.⁵²

A systematic review of randomized controlled trials on the use of human albumin solution in critically ill patients suggested that albumen administration might be deleterious and increase mortality.⁵³

Hypertonic saline has been repeatedly advocated as a burn resuscitation fluid as the hypertonicity of the infused fluid helps shifts water from the intracellular space into the extracellular compartment. This expands the intravascular space and leads to less fluid administration and less oedema. Unfortunately, this promising approach has not found consensus due to difficulties with composition and concentration of the hypertonic solutions and complications such as hypernatraemia.⁵⁴

Fluid resuscitation endpoints

Endpoints in resuscitation are crucial and will differ for different patients and injuries. Clinical endpoints used routinely in the majority of patients undergoing resuscitation include pulse, blood pressure, respiratory rate, capillary refill, core/peripheral temperature gradient, urine output and osmolality.

The fluid infusion rate should be adjusted to achieve a urine output of 0.5–1 mL/kg/h in adults and 1–1.5 mL/kg/h in children, but it has been debated whether this ideal output should be based on actual body weight or predicted body weight.

Measures such as invasive haemodynamic monitoring of blood pressure, central venous pressure, pulmonary artery wedge pressure and cardiac output can also be used in patients with larger injuries and/or with concomitant smoke inhalation to give more information. Oesophageal Doppler measurement of haemodynamic parameters is a minimally invasive technique that is now routinely used to monitor adequacy of fluid therapy in larger burns.

Serial arterial blood gas estimation with particular reference to the base excess and serum lactate offer an accurate evaluation of adequacy of resuscitation. The persistent elevation or failure to correct these markers of tissue perfusion is associated with increased morbidity and mortality.⁵⁵

Complications of fluid resuscitation

Increased fluid requirements are recognized following delayed or inadequate resuscitation, deep burns, petrol burns, high-voltage electrical burns, alcohol intoxication, extensive deep burns and inhalation injury in children and the elderly.^{56,57}

Under-resuscitation can give rise to hypovolaemia, shock, renal failure, ischaemia–reperfusion injury and multiple organ failure. Over-resuscitation can lead to generalized oedema, pulmonary oedema and compartment syndromes occurring in the limbs and the abdomen.

‘Fluid creep’ can be defined as the unpredictable trend toward ever increasing resuscitation fluid volumes in burn patients. The consequences of increased fluid administration include airway swelling requiring prophylactic intubation, abdominal and extremity compartment syndromes that require escharotomy/fasciotomy and increased mortality.⁵⁸

Intra-abdominal hypertension and the abdominal compartment syndrome have become increasingly reported and are associated with a high morbidity and mortality. Intra-abdominal pressures can be measured by transduction of bladder pressures and intra-abdominal hypertension is defined as pressure greater than or equal to 12 mmHg. Abdominal compartment syndrome can be defined as an intra-abdominal pressure greater than 20 mmHg with new organ dysfunction. Abdominal compartment syndrome is associated with haemodynamic instability, oliguria and renal failure, impaired mechanical ventilation with high peak airway pressures, and a worsening metabolic acidosis.⁵⁹

In major burn injuries, particularly those requiring excessive fluid administration, transduction bladder pressure should be monitored regularly.

Methods to reduce intra-abdominal pressures include extension of anterior trunk escharotomies, neuromuscular relaxants and increased sedation in ventilated and possible judicious use of diuretics in patients demonstrating adequate intravascular volumes. Peritoneal dialysis catheters to remove peritoneal fluid have also been used. If the abdominal compartment syndrome is non-responsive then a decompressive laparotomy or laparoscopy should be considered, although mortality following surgical decompression is high.⁶⁰

It is not entirely clear why ‘fluid creep’ occurs but it may be related to clinical inattention to fluid resuscitation, patients surviving larger/deeper burns that require more fluid, the near abandonment of colloid in the first 24h post injury, a physiological cycle of oedema generation and increased use of opioids.⁵¹

Following fluid resuscitation, burn patients have significant ongoing metabolic fluid requirement due to hypermetabolism, pyrexia and evaporative wound losses. The daily requirement can be calculated and should be given enterally if possible.

Ongoing management

Hypermetabolism and nutrition

Major burn injury impairs the ability to regulate core body temperature, leading to profound heat and evaporative water loss. The hypermetabolic response increases core and skin temperatures 1–2°C above normal in compensation. Patients unable to mount this response are either septic or have exhausted physiological reserve.

Wilmore and colleagues showed that the hypermetabolic response can be attenuated by increasing ambient temperatures to 33°C, regarded as a thermally neutral temperature. Maintaining ambient temperatures between 28°C and 33°C reduces resting energy expenditures in burn patients by a magnitude of 2.⁶¹

Early excision and grafting for major burns has been shown to decrease the metabolic rate for patients totally excised and covered within 3 days of injury compared with those patients excised and covered at one week. The reduction in metabolic rate prevents further net protein loss and catabolism. In addition, early excision has been shown to reduce log bacterial counts in quantitative tissue cultures when compared to late wound excision. This is associated with a reduction in the incidence of sepsis. It can be seen by these mechanisms that early excision and grafting both directly and indirectly attenuates the hypermetabolic response.⁶²

Aggressive, early enteral feeding improves outcomes in severely burned patients. Enteral feeding using 25 kcal/kg body weight and 40 kcal per % TBSA burn per day will maintain body weight in burned adults.⁶³ Children require 1800 kcal/m² plus 2200 kcal/m² of burn area per day.⁶⁴ Enteral nutrition preserves first-pass nutrient in the liver, reduces bacterial translocation with associated sepsis and maintains gut motility.

Enteral nutrition is safer and more effective than parenteral nutrition, which is reserved for those with enteral feeding intolerance or prolonged ileus. Parenteral nutrition alone or in combination leads to overfeeding, liver failure, impaired immune response and increased mortality.⁶⁵

There are many nutritional formulas available to calculate energy requirements of burn patients, however it has been demonstrated that a significant number of these will provide more calories than required (Table 14.3).

By measuring resting energy expenditures, actual caloric requirements can be determined. Overfeeding can lead to significant problems, including elevated respiratory quotients, hypercarbia, increased fat synthesis, fatty deposition in the liver and hyperglycaemia, particularly when excessive carbohydrate is given.⁶⁶ This can give rise to problems with ventilation and prolonged weaning.

Indirect calorimetry can be used to measure resting energy expenditure at the bedside and nutritional calorie requirements can be calculated using 1.2–1.4 times measured resting energy expenditures.⁶⁷

Burn patients require a minimum of 1.5–2 g/kg body weight per day of protein intake to maintain lean body mass. High-fat diets result in protein breakdown and limited lean body mass gains when compared with high-carbohydrate diets consisting of 3% fat, 15% protein and 82% carbohydrate. Burn patients

benefit from a high-carbohydrate diet resulting in increased protein synthesis and improved lean body mass.⁶¹

Burn patients demonstrate significant functional limitations and often struggle to progress with rehabilitation. Exercise training can increase lean body mass, improves strength and stamina and improves overall cardiopulmonary capacity. A 12-week resistance and aerobic exercise training programme has been shown to improve muscle strength, lean body mass and power compared with standard of care.⁶⁸

Pharmacological modulation

Recombinant human growth hormone (rhGH) has been shown to significantly improve outcomes in severely burned children when given intramuscularly at a dose of 0.2 mg/kg/day. Growth hormone was shown to decrease skin graft donor site healing times, length of stay, and total cost of care and improve scar quality.⁶⁹

Unfortunately these benefits have not been demonstrated in adults, where an increased mortality rate in non-burned critically ill adults has been reported, although currently it is thought to be safe to use rhGH in paediatric burn patients to attenuate the hypermetabolic response. The most notable side effect is hyperglycaemia, which requires close monitoring.⁷⁰

Testicular steroid production is decreased in severely burned patients and contributes to the loss of lean body mass seen.

Table 14.3 Formulas for nutritional requirements of burned patients

ADULTS		
1. Calculate BMR		
Patient's age:	Males (kcal/day)	Females (kcal/day)
15–18 years	17.6 W + 656	13.3 W + 690
18–30 years	15.0 W + 690	14.8 W + 485
30–60 years	11.4 W + 870	8.1 W + 842
Over 60 years	11.7 W + 585	9.0 W + 656
2. Adjust BMR for stress		
Multiply by a factor for burn size:		
Partial-thickness burn	Add 1% for each 1% BSA (e.g. for 40% partial thickness × 1.4)	
Full-thickness burn	Add 2% for each 1% BSA (e.g. for 40% full thickness × 1.8)	
To a maximum of 50% BSA		
3. Add a combined factor for activity and diet-induced thermogenesis		
Ventilated patient	×1.1	
Bedbound but not ventilated	×1.2	
Mobile on ward	×1.25	
CHILDREN		
The recommended formulas are based on body surface area:		
Child's age	Daily requirements (kcal/day)	
0–1 year	2100 kcal/m ² (SA) + 2100 kcal/m ² (BSA)	
1–11 years	1800 kcal/m ² (SA) + 1300 kcal/m ² (BSA)	
12–18 years	1500 kcal/m ² (SA) + 1500 kcal/m ² (BSA)	
1. Formula for body surface area (SA):	SA (m ²) = √[(height (cm) × weight (kg))/3600]	
Or use surface area nomogram		
2. Formula for BSA in calculation:	BSA = [% burn × body surface area (SA)]/100	

W, weight in kg; BSA, burn surface area.

Testosterone can only be given by intramuscular injections and has a virilizing effect, limiting its use. Oxandrolone, a synthetic analogue, offers only 5% of the masculinizing effects of testosterone, and is safe for both genders. Oxandrolone improves net muscle protein synthesis and protein metabolism in severely burned patients when administered at a dose of 0.1 mg/kg twice daily. It has been shown to improve donor site healing times, decrease length of stay, increase protein synthesis, increase lean body mass, increase bone mineral content and increase muscle strength.⁷¹

Propranolol used at a dose of 0.5–4 mg/kg per day to reduce resting heart rates by 10–20% blocks beta-adrenergic stimulation, reducing the effects of elevated levels of catecholamines. This decreases tachycardia, cardiac work and basal metabolic rate. It also prevents increased peripheral lipolysis, decreases fatty infiltration of the liver and inhibits the release of free fatty acids from adipose tissue. In addition, it increases lean body mass and decreases skeletal muscle wasting.⁷²

Hyperglycaemia leads to muscle protein catabolism, reduced graft take, and increased morbidity and mortality. Intensive insulin therapy of 400–900 mU/mL to maintain euglycaemia for 7 days has been shown to stimulate muscle protein synthesis and increase lean body mass, improve donor site wound healing and reduce hospital stay. Less rigorous control of glucose levels with insulin has demonstrated similar benefits with a decreased risk of treatment-related hypoglycaemia, which approaches 20% with high-dose insulin regimes.⁷³

Other drugs such as fenofibrate, glucagon-like peptide-1 and ketoconazole have also been investigated for attenuation of the hypermetabolic response.⁶¹

Pain

Burn injury is usually associated with significant amounts of pain and anxiety and pain control in burn patients is essential and difficult task that is often inadequately performed. Adequate pain relief must be given both for background pain and procedural pain control. Anxiety can be equally debilitating and can be controlled with anxiolytics. Requirements for pain relief, sedation and anxiolysis vary depending on the individual patient, the size, site and stage post injury. Pharmacological techniques include the use of opiates for pain and benzodiazepines for sedation and anxiolysis. Ketamine, a neuroleptic agent, is particularly useful for procedures especially in children and can be given orally using nurse-led protocols. Centrally acting agents such as the tricyclic antidepressants, clonidine and gabapentin have a role to play in modulation of the pain response. Non-steroidal anti-inflammatory agents are useful but care must be taken in the acute phase and in elderly patients due to the risk of renal impairment and gastrointestinal haemorrhage.

Pain and anxiety can be measured using scoring systems. Regular, ongoing and documented pain assessment is vital to

the ongoing management of burn pain. Children can pose a particularly difficult management problem. Large doses of analgesics and sedatives are sometimes required due to hypermetabolism of the drugs and tolerance. Non-pharmacological interventions such as relaxation therapy, hypnotherapy and distraction can also be useful in helping control pain and anxiety.

Pain specialists are an integral part of the modern burn multidisciplinary team and pain control must be given a high clinical priority.⁷⁴

Sepsis, antibiotics and topical antimicrobials

Infection is a common, serious and potentially life-threatening complication following burn injury. The reported incidence of nosocomial infections varies between 63 and 240 per 1000 patients and 53–93 per 1000 patient days. Infections are associated with multiple organ failure, increased morbidity and mortality.⁷⁵

The burn wound is usually sterile for the first 6–12 h following the injury. It becomes contaminated then colonized with bacteria.⁷⁶ In the first week or so following injury gram-positive bacteria predominate with gram-negative bacterial infections being most common after that time. The source of these microorganisms is thought to be exogenous from the environment or cross-infection from staff. Alternatively, it can be endogenous from adjacent colonized uninjured skin, bacterial translocation from the gut or from direct faecal self-contamination. Burn patients are known to be immunocompromised and to have a high incidence of nosocomial infection. They often require intensive care support, making them prone to ventilator-associated pneumonia and catheter-related infections.⁷⁷

Microbiological surveillance of the burn wound is essential. This involves regular swabbing of wounds and cultures of sputum, urine and blood. Wound swabs inform clinicians as to what surface organisms are present but do not always inform as to what is happening at the eschar/viable tissue interface. Quantitative microbiology is thought to be invaluable in determination of numbers of organisms per gram of tissue but is labour intensive and may be prone to sampling error. It is common to find 10^3 – 10^5 organisms per gram of burn tissue and counts greater than 10^5 are indicative of invasive infection.⁷⁸

The current literature suggests that prophylaxis with systemic antibiotics should not be given to patients with severe burns. This consensus is based on the lack of evidence of benefit and risk of adverse effects. A recent meta-analysis of antibiotic prophylaxis indicated a reduction in the mortality risk in burn patients although the methodological quality of the data analysed was questionable.⁷⁹

Antibiotic prophylaxis may be given to patients undergoing surgical procedures when there is a significant incidence of bacteraemia. The antibiotic given and duration of therapy depend on the time following the injury, the surgical procedure being

Box 14.2 Definition of sepsis and infection in burn patients includes at least three of the following parameters. Source: Greenhalgh et al., 2007.⁸⁰ Reproduced with permission of Lippincott Williams & Wilkins.

- Temperature >102.2°F (39°C) or <97.7°F (36.5°C)
 - Progressive tachycardia (e.g. adults >90 beats per min; children >2 standard deviations [SD] above age-specific normal values)
 - Progressive tachypnoea (e.g. adults >30 breaths per min; children >2 SD above age-specific normal values)
 - Refractory hypotension (e.g. adults: systolic blood pressure <90 mmHg or a decrease >40 mmHg, or mean arterial pressure <70 mmHg; children <2 SD below normal)
 - Leukocytosis (e.g. adult >12 000 white cells/μL, children >2 SD above normal) or leukocytopenia (e.g. <4000 white blood cells/μL)
 - Thrombocytopenia that occurs 3 days after resuscitation (e.g. adults <100 000 platelets per μL; children <2 SD below age-specific normal values)
 - Hyperglycaemia >110 mg/dL (6.1 mmol/L) in the absence of pre-existing diabetes mellitus
 - Inability to tolerate enteral feedings for more than 24 h based upon:
 - ♦ abdominal distention
 - ♦ residual volumes (two times the feeding rate in adults and >150 mL/h in children)
 - ♦ uncontrollable diarrhoea (>2500 mL/day for adults and >400 mL/day for children)
- The infection must be documented by one of the following evaluations:
- Infection is confirmed on a culture (e.g. wound, blood, urine), or
 - Pathologic tissue source is identified (>10⁵ bacteria on quantitative wound tissue biopsy or microbial invasion on biopsy), or
 - A clinical response to antimicrobial administration is documented.

undertaken and the results of microbiological surveillance and advice from a microbiologist.

The diagnosis of sepsis can be difficult in the burn patient. They are typically hypermetabolic, hyperpyrexial, tachycardic, tachypnoeic, and have an elevated white blood cell count. Clinical indicators of burn sepsis are given in Box 14.2.⁸⁰

Examination of the burn wound can reveal erythema, progressive focal necrosis, eschar separation, punctate haemorrhages and progression of burn wound depth. In addition, wound odour and subeschar pus may be present. Ecthyma gangrenosum, an aggressive pseudomonal infection, can present with black lesions in the wound and surrounding skin.

Blood cultures typically have a low yield rate but although approximately 20% of patients in a burn ICU will have positive cultures, these are associated with 20% mortality. Such positive cultures can be difficult to interpret due to contamination with commensal organisms.⁸¹

Vascular access in patients can be a significant challenge and a risk in terms of catheter-related bloodstream infections. Central venous catheters in burn patients are changed every 7 days or so following insertion, either to a new site or over a guidewire, with a recent study showing no difference in the incidence of bloodstream infections between the two methods.⁸² Other studies have shown increasing incidence of sepsis associated with increasing number of line days and line changes with no difference between line sites.⁸³

Intensive care bundles of care have been popularized and have benefits in burn patients in the ICU. Implementing care bundles into the burn critical care setting has been associated with reduction in ventilator-associated pneumonias, bloodstream infection rates and a lower mortality.⁸⁴

Suppurative thrombophlebitis is a rare but serious infective complication of peripheral intravenous cannulas. It typically gives rise to a clinical picture of sepsis and persistent positive blood cultures with skip lesions of infected foci with normal vein in-between. Pus can be expressed from the affected vein and treatment requires excision of the vein.⁸⁵

The management of systemic sepsis involves fluid resuscitation, immediate intravenous antibiotics and source control in the form of excision of infected wounds. Antibiotic therapy should be guided by previous cultures and sensitivities and close liaison with the microbiologist is essential. Care must be taken to avoid the use of multiple broad-spectrum antibiotics that can lead to the emergence of resistant organisms.

Infection control is a very important part of care within a burns unit. Cross-infection should not be tolerated and can be eliminated by effective infection control and cohort nursing. Washing wounds in a shower reduces the bacterial load and topical antimicrobials limit bacterial growth. The introduction of topical antimicrobial agents in burn care in the 1970s was thought to lead to a significant reduction in burn mortality, but recent systematic reviews have highlighted the paucity of data.⁸⁶

Topical agents currently used include silver-containing products active against *Staphylococcus aureus*, *Pseudomonas aeruginosa*, enteric organisms and *Candida albicans*.

Povidone-iodine has broad antibacterial and antifungal activity but a short duration of activity. Mupirocin (Bactroban®) is effective against gram-positive organisms (especially MRSA) with some activity against gram-negative organisms. Nystatin is an effective antifungal agent that can be used topically to reduce fungal wound infection and orally to prevent gut colonization. Hypochlorite has a broad spectrum and is bactericidal against *Ps. aeruginosa*, *Staph. aureus* and other gram-positive and negative organisms. Used at lower concentrations (0.025%) it is toxic to bacteria but not to human cells.⁸⁷

Complications

Patients with major burn injury are a high-risk group for developing complications.

Goal-directed resuscitation, early wound excision and recognition and modulation of the hypermetabolic response have reduced morbidity and mortality. Multiple organ dysfunction in burn injuries >20% TBSA has been reported to have an incidence of 40–60% and mortality rates are proportional to the numbers of organ failures.⁸⁸ The majority of complications are related to sepsis and the systemic inflammatory response, although specific complications can occur in each physiological system.

Organ dysfunction

Patients with a significant burn injury with or without smoke inhalation will exhibit a spectrum of clinical manifestations of systemic inflammation that range from systemic inflammatory response syndrome (SIRS) through to sepsis, severe sepsis and septic shock (Table 14.4).

Tissue damage is the precipitating event for systemic inflammation caused by direct thermal injury or by ischaemia–reperfusion. Tissue injury results in the release of proinflammatory cytokines such as tumour necrosis factor alpha, interleukins IL-1, IL-6, IL-8, IL-12, IL-18 and interferon beta. Other causes of SIRS include sepsis, ischaemia–reperfusion injury, multiple trauma and pancreatitis.¹⁷

Some patients with SIRS will go on to develop multiple organ dysfunction syndrome (MODS), where non-fatal organ dysfunction develops, such as renal insufficiency, inotrope or ventilator dependence. Some of these patients with MODS will go on to full blown multiple system organ failure (MSOF), which is often fatal. It is not clear what factors escalate this chain of events, but gut failure with repeated bouts of bacterial translocation has been postulated as one cause.⁸⁸

Cardiac function alters in a number of ways, including initial reduction in preload with myocardial depression leading to decreased in cardiac output. A hyperdynamic phase follows, characterized by decreased afterload due to a lowered systemic vascular resistance and a subsequent increased cardiac output. Depending on the clinical picture, fluid administration to increase intravascular volume and/or inotropic support may be required.¹⁷

Initially following burn injury coagulation factors are diluted and consumed, leading to derangement of clotting indices and increased fibrin degradation products, although frank coagulopathy is uncommon. The coagulation cascade is activated; fibrin, factors V and VIII increase and antithrombin deficiency is common. Later on there is tendency for patients to be hypercoagulable, leading to deep vein thrombosis and pulmonary embolism.⁹⁰ Thrombocytosis in the later stages of wound healing and recovery is common. Venous thromboembolic prophylaxis should be considered following the initial phase of burn injury. The placement of precious central venous catheters must be carefully considers as the femoral site, which is often the only available vascular access site in a

major burn, has been associated with a significant incidence of thrombosis.

Mechanical ventilation in a burn patient may be required for upper and lower airway inhalation injury, although respiratory failure and hypoxia due to acute lung injury can also occur in burn patients without inhalation injury. This can lead to acute respiratory distress syndrome (ARDS). This clinical condition presents as dyspnoea, severe hypoxia and decreased lung compliance with radiological changes of bilateral diffuse pulmonary infiltrates. Burn patients can sustain lung injury both directly following smoke inhalation and also because of the systemic inflammation triggered by the cutaneous burn injury.

Typically, a patient with a severe burn with or without an inhalation injury will be intubated for airway compromise or for operation. At 4–5 days following injury oxygenation will deteriorate, requiring higher inspired oxygen concentrations to prevent hypoxia. Lung compliance will increase, requiring higher inflation pressures, and at 7 days post burn lung infiltrates will appear on the chest X-ray.

Treatment is mainly supportive until the fibrotic process ceases. Protective ventilation strategies should be employed to reduce barotrauma.⁹¹ Steroid treatment has been shown to be of no benefit in prevention of ARDS following smoke inhalation injury.

Pneumonia is a common complication following smoke inhalation injury and is usually caused by a variety of organisms including *Ps. aeruginosa*, *Klebsiella pneumoniae* and *Staph. aureus*. Prophylactic antibiotics do not prevent infection in patients and are a risk for promoting growth of multiple drug-resistant organisms.⁹²

Diagnosis of pulmonary infection following smoke inhalation can be difficult, as many patients will have a systemic response. However clinical signs and symptoms, deteriorating gas exchange, worsening chest X-ray appearance, sputum cultures and bronchoalveolar lavage are all important features in the diagnosis.

Once the diagnosis is made or considered, early institution of broad-spectrum antibiotics, close liaison with the microbiologist and antibiotic stewardship to match organism sensitivities are crucial.

Long-term airway and pulmonary complications can result from smoke inhalation injury and its treatment.⁹³ These include glottic, subglottic and tracheo-bronchial complications. Pulmonary

Table 14.4 Definitions of SIRS, sepsis, severe sepsis, septic shock and MODS

SIRS Criteria (≥2 meets SIRS definition)	Temp >38°C (100.4°F) or <36°C (96.8°F) Heart rate >90 Respiratory rate >20 or PaCO ₂ <32 mmHg WBC >12 000/mm ³ , <4000/mm ³ , or >10% bands Suspected or present source of infection
Sepsis criteria (SIRS + source of infection)	Lactic acidosis, SBP <90 or SBP drop ≥40 mmHg of normal
Severe sepsis criteria (organ dysfunction, hypotension, or hypoperfusion)	Severe sepsis with hypotension, despite adequate fluid resuscitation
Septic shock criteria	Evidence of ≥2 organs Failing
Multiple organ dysfunction syndrome (MODS) criteria	

Source: Dellinger et al., 2012.⁸⁹ Reproduced with permission of Lippincott Williams & Wilkins.

function test, laryngoscopy and bronchoscopy allow detection and management of the complications. The plastic surgeon must be mindful and alert to these issues when planning surgical reconstruction requiring general anaesthesia.

Gastrointestinal events that initially follow burn injury include splanchnic hypoperfusion, mucosal atrophy, altered absorption and increased intestinal permeability. These all lead to diminished gut barrier function. Feeding intolerance, mucosal ulceration and bleeding from the stomach and duodenum manifest this. Diminished gut barrier function is also thought to lead to bacterial translocation, which stimulates the systemic inflammatory response.⁹⁴

These changes can be attenuated by judicious fluid resuscitation and early enteral nutrition. Early enteral feeding increases splanchnic blood flow, maintains pyloric function and intestinal motility and reduces infective complications.⁹⁵

Poorly perfused organs lead to acidosis, leading to increased fluid administration. Overzealous fluid administration can lead to intra-abdominal hypertension (>15 mmHg) and compartment syndrome (>20 mmHg).⁵⁹

Stress ulcer prophylaxis is also maintained by either reduction of gastric acid production with histamine blockers (ranitidine) or proton pump inhibitors (omeprazole). Gastrointestinal haemorrhage in a burn patient is now uncommon.

Renal failure due to failure of initial resuscitation is uncommon, however is more commonly seen as part of a multiple organ failure syndrome. The incidence is reported to be up to 20%, with an incidence of renal failure requiring renal replacement being 15%. The mortality associated with renal failure following burn injury has been reported to be from 50 to 100%.⁹⁶

In major full-thickness injury and high-voltage electrical injury, red blood cell and muscle destruction can lead to haemoglobinuria, myoglobinuria and acute tubular necrosis. This can be avoided by aggressive fluid resuscitation aiming for a urine output of 1–2 mL/kg per h. Additional therapies include alkalization of the urine and the use of an osmotic diuretic (mannitol).

Later onset renal failure is usually part of multiple organ failure secondary to sepsis and/or the systemic inflammatory response. It can also occur following administration of nephrotoxic drugs.

Management involves treatment of the underlying cause and early renal replacement therapy, either by haemofiltration or dialysis. The mortality associated with renal failure remains high, especially in the group associated with multiple organ failure.

Electrolyte disturbances are common following major burn injury. Hypernatraemia in the resuscitative phase is usually indicative of both over- and under-resuscitation. Hyponatraemia is not uncommon following resuscitation of children and is usually due to over zealous administration of hypotonic solutions such as 5% dextrose or dextrose saline. It can lead to hyperpyrexia, cerebral oedema and convulsions. In the late burn phase

hypernatraemia may occur due to excessive water losses and inadequate replacement. Hyperchloraemia is not uncommon following resuscitation, due to the significant amount of chloride-containing fluids administered. Burn patients have a significant requirement for phosphate and magnesium due to exudative losses and urinary excretion.⁹⁷

Hypocalcaemia can occur following resuscitation and requires intravenous supplementation. Hypercalcaemia is underrecognized, can be associated with renal failure and has been associated with increased mortality.⁹⁸

It is important to ensure that metabolic requirements following a burn are given enterally and that particular attention is paid to fluid balance on a daily basis.

Great care must be taken in positioning and prevention of peripheral nerve compression during the acute care of burn patients. Isolated peripheral neuropathy, either idiopathic or due to entrapment or compression, can hinder functional outcome. In addition, patients surviving major burn injury can develop a generalized critical care neuropathy characterized by global weakness that can prolong ventilator dependence, mobilization and rehabilitation. Risk factors for critical care neuropathy include multiple organ failure, muscular inactivity, hyperglycaemia and use of neuromuscular blockers. Early mobilization and exercise may help prevent or reduce severity of this problem.⁹⁹

Patients surviving major burn injury become osteopenic due to prolonged immobilization and hypermetabolism. This is as a result of alterations in calcium and phosphorus metabolism. Bone formation is reduced, with a reduction in bone mineral density, leading to an increased incidence of fracture, decreased growth velocity and growth stunting.¹⁰⁰

In the recovery phase, heterotopic ossification can cause periarthral ossification and limitation of movement, which can hinder rehabilitation. An aggressive approach of early surgery and wound healing with early active mobilization has reduced the incidence of this problem.

Wound management

Treatment planning

In general, burn injury and its attendant consequences are directly related to the size and depth of the burn wound. It is evident that treatment planning is key to successful management of burn injury.

The management plan depends on the depth and size of the injury, the anatomical distribution, the age and comorbidities of the patient and involves both conservative and surgical options.

Superficial partial-thickness wounds require a conservative approach, whereas an aggressive surgical approach is best for deeper wounds. The aim of such a treatment plan is to improve outcome and reduce morbidity in smaller injuries and to improve survival in bigger injuries.

Superficial partial-thickness wounds

The aim of management of superficial partial-thickness burn wounds is to promote rapid spontaneous re-epithelialization with the minimum number of painful dressing changes. In addition, prevention of infection to minimize deepening of the burn wound and subsequent hypertrophic scarring are also important.

The wounds can be treated with conventional dressings, either impregnated or free from a topical antimicrobial agent, with topical antimicrobials, with biological or semi-biological dressings or by exposure.

Conventional dressings, such as Vaseline gauze or silicone sheets (Mepitel®), can be used to dress the wound while re-epithelialization occurs and are useful for small burns (less than 5% TBSA). These dressings tend to require frequent changes which can be painful. Many synthetic dressings, such as Duoderm®, Omniderm®, Tegaderm® and hydrocolloids have also been used with success to dress such wounds. A recent Cochrane review highlighted the paucity of high-quality data on dressings for superficial and partial-thickness burn injury and that the available evidence was of limited usefulness in aiding clinicians to choosing suitable treatments.¹⁰¹

The antimicrobial properties of silver have been long recognized and many silver-containing dressings are currently used for the management of burn wounds. Traditionally, topical 1% silver sulfadiazine (Flamazine®/Silvadene®) cream has been the mainstay of treatment for these wounds. Following cleaning and debridement of the wound, the cream is applied and covered with a conventional dressing. The dressings are changed once or twice daily until re-epithelialization occurs and the wound is healed.

Acticoat® is a nanocrystalline silver dressing that can provide sustained release of silver for up to 7 days, with studies showing Acticoat to have better antimicrobial activity than silver sulfadiazine. Other studies have suggested Acticoat having fewer adverse effects, reducing healing times, improved ease of application and low frequency of dressing changes.¹⁰²

Treatment with a topical antimicrobial is useful for patients presenting late after injury with a colonized wound.

A biological dressing can be defined as the use of human or animal tissue for temporary wound covering. A semi-biological dressing refers to where a component of the dressing is derived from such tissue (i.e. collagen).¹⁰³

Biobrane® is a semi-biological dressing made up of a fenestrated silicone layer bonded to a nylon mesh that has been impregnated with type I porcine collagen. Repeated studies have shown it to reduce pain, inpatient stay and time to healing.¹⁰⁴ Biobrane® has been used extensively in patients with superficial partial-thickness burns presenting within 24h of their injury. Under sedation or an anaesthetic the burn blisters are cleaned, deroofed and all burned epithelium is removed. Biobrane is then applied to the wound so that it is closely adherent. The Biobrane can be secured by histoacryl glue, sterile Hypafix® tape or with staples. A standard secondary dressing of rolled gauze covered by elastic bandages is then applied. The outer

dressings are removed at 24–48h to inspect the wound. Oral antibiotics with staphylococcal coverage are usually given. As re-epithelialization occurs in 10–14 days, the Biobrane spontaneously separates from the healed wound. If wound infection supervenes, the Biobrane rapidly becomes non-adherent. Purulent exudate produced by the wound is then readily visible. Biobrane is not used in patients with delayed presentation and potential colonization arriving more than 24–36h following injury. Biobrane is also relatively expensive compared to other dressing modalities.¹⁰⁴

Other biological dressings such as allograft skin, xenograft skin (porcine) and human amnion are used in a similar fashion to Biobrane to physiologically close the superficial partial-thickness wound while re-epithelialization occurs. The problems associated with the use of these products include availability, collection, storage, transmission of infection and cost.¹⁰³

Exposure of the burn wound has fallen out of favour but has been extensively used in the past. After cleaning and debridement, wounds are nursed exposed in a warm dry environment and left to crust over. The coagulum formed separates as re-epithelialization proceeds until healing occurs. Exposure is comfortable and dressing changes are not required. Disadvantages include prolonged inpatient treatment, requirement of a specialized humidified environment, electrolyte disturbances and higher infection rates. This technique has now generally been abandoned apart for specific areas that are difficult to dress, such as the face, genitalia and perineum.

Large superficial partial-thickness injuries (>40% TBSA) carry a higher risk of wound contamination and infection, leading to organ dysfunction and morbidity.

The use of allograft applied within 24h of the injury has been reported as improving outcome. Following cleaning and debridement of loose epidermis under anaesthesia, allograft split-skin grafts are placed over the open dermal wound. Similarly a mid-dermal burn injury can be debrided with a dermatome at a depth of 10–15/1000 inch and allograft applied. Standard graft dressings are applied and spontaneous healing should occur with allograft separation as the wound epithelializes.¹⁰⁵

Xenograft skin¹⁰⁶ and Biobrane can be used in a similar fashion but are associated with an increased risk of desiccation, infection and deepening of the burn wound. Topical antimicrobials such as silver sulfadiazine or Acticoat can be used for this type of wound, especially for wounds that present late and are colonized. Dressing changes in these circumstances can be painful. There is a significant incidence of wound sepsis and deepening of the burn wound necessitating skin grafting.

Deep partial-thickness wounds

Deep partial-thickness burns are associated with significant morbidity in terms of time to healing, infective complications and subsequent scarring. Conservative management leading to spontaneous healing usually involves prolonged and painful dressing changes and the resultant scar is invariably hypertrophic.

This leads to disfigurement and functional disability. An optimal approach is early surgery that tries to preserve dermis and achieve prompt wound healing.¹⁰⁷

Burns that are deemed to be deep partial thickness in nature are best tangentially excised and the wound covered with autologous split-skin grafts that usually require meshing. Cosmetically and functionally sensitive areas such as the face and hands need thicker sheet autograft for wound closure.

Allograft, xenograft or other biological or semi-biological dressings may be required for temporary wound closure if donor sites are scarce, to allow time for donor site healing. Alternatively serial wound excision with conservative management of the unexcised wound can be used for larger burns where donor sites are scarce. Unexcised areas are treated with topical antimicrobials until donor sites can be reharvested, usually at 7–14 days.

The unexcised and unhealed areas of burn wound are susceptible to invasive wound infection, with associated increase in morbidity and mortality. Topical Flammacerium® (silver sulfadiazine and cerium nitrate) has been reported as decreasing episodes of invasive wound infection, morbidity and mortality with this conservative method of treatment.¹⁰⁸

Alternatively, deep partial-thickness wounds can be treated with Acticoat; alternate day to weekly dressing changes can be used. Daily or twice daily application of silver sulfadiazine until wound healing is achieved has largely been abandoned for this type of wound. The wounds may take 4–6 weeks to heal, with an a higher incidence of invasive wound infection, deepening of the wound and hypertrophic scarring. More conservative methods are reserved for patients who are unfit for surgical intervention and for smaller burns in functionally and cosmetically unimportant areas.

Full-thickness wounds

Full-thickness burns require excision and will not heal spontaneously unless they are very small. The resultant wounds require closure to reduce the risks of invasive infection and systemic sepsis and invariably require skin grafting. Prompt excision and wound closure reduces morbidity and mortality in patients with such injuries.^{109,110}

These wounds should be excised in a tangential fashion wound and closure obtained with split-thickness autograft. Sheet autograft is used for functionally and cosmetically sensitive areas such as the hands and face. Meshed autograft is used if larger areas need closure. Grafts are secured to the wounds by staples or absorbable sutures and are dressed in the standard fashion. Grafts and wound inspection is undertaken on the second day if the initial wound was infected or heavily colonized or on the fifth day if not.

Patients who are elderly or unfit for surgical intervention can undergo conservative management with topical antimicrobials. The antimicrobial agent – Acticoat® or silver sulfadiazine – is applied regularly until the burn eschar separates and a granulating wound is present. This usually takes approximately

3–4 weeks to occur and sometimes longer. This granulating wound can then be covered with autograft to achieve wound closure. Other topical agents such as Flaminal® or Nexobrid® can also be used to aid eschar separation. In certain cases small wounds less than 5 cm diameter can be left to heal spontaneously by wound contraction and epithelialization from the wound margins.

In larger injuries (>10% TBSA) most authors agree that early excision of the burn wound is the treatment of choice. However, the timing varies from immediate excision soon after arrival in the burn service to staged excision over the first 7 or so days following admission. Unfortunately, no evidence exists as to optimal timing or extent of early wound excision.

Total early excision of the burn wound, within 24 h of injury, and physiologic wound closure with split-skin autograft, allograft and/or synthetic skin substitute approach has been shown to improve mortality in selected adult patient groups.¹¹¹ It needs a coordinated approach from the surgical and anaesthetic teams, and timing of surgery post injury is critical as blood loss in the 24 h post burn has been shown to be half that of surgery after this time.¹¹²

Following total wound excision, the whole wound must be physiologically closed with auto- or allograft or a synthetic skin substitute. Autograft is widely meshed and used with allograft overlay in a sandwich technique. Areas not closed with autograft have allograft applied to close the wound. If wound closure cannot be achieved primarily with autograft, the patient returns to the operating room when the donor sites are ready for reharvesting, at which time the allograft is changed and further autograft is applied. This is usually done in stages on a weekly basis until the whole wound is closed with autograft.

A more traditional conservative surgical approach has been described above for deep partial-thickness burns and entails excision of as much of the wound that can be covered with available autograft, with the unexcised areas of burn treated with topical antimicrobials. This method of treatment has a higher morbidity and mortality in larger injuries and has generally been abandoned.

Preoperative planning is essential with anatomical areas to be debrided, technique used for debridement and choice of donor sites being the key elements in the treatment plan. It is essential to estimate the amount of autograft that will be required, which areas are priorities for autograft coverage and any required mesh ratios.

In smaller burns where donor sites and available graft are plentiful, the focus of treatment should be to minimize donor site morbidity and to maximize functional and cosmetic outcome. Sheet grafts are preferred and preferential harvest of cosmetically hidden areas such as the upper thighs, buttocks and scalp should be considered. The scalp is an attractive donor site, as subsequent hair growth completely hides any marks. In patients with major burn injury, choice of donor sites is limited and skin grafts should be harvested from any available site as

priority is given to cover large areas with available autograft in the smallest number of operations.

Techniques of wound excision

Wound excision is key to accurate removal of non-viable tissue. Preservation of viable dermis is important in partial-thickness injury, whereas in full-thickness injury all necrotic and infected tissue must be removed. The aim of debridement is to leave a viable wound bed of dermis, fat, fascia or muscle that will accept a skin graft.

Enzymatic wound debridement has recently been regaining popularity, with the development of newer agents that have been shown to be effective.¹¹³

The combination of non-surgical debridement techniques with cellular skin replacement therapies seems to be the logical direction of travel for future burn wound management.

Tangential excision of the burn wound was described by Janzekovic in the 1970s and involves repeated shaving of partial-thickness burns in a tangential fashion until a viable dermal bed, manifested clinically by punctate bleeding, is achieved.¹⁰⁷ If the wound extends down into fat, its colour can be helpful as a sign of viability ('red fat being dead fat') in addition to punctuate bleeding and thrombosed vessels. After haemostasis the wound is ready for grafting. Full-thickness wound excision can also be achieved using sharp excision with a knife or with electrocautery. The plane of excision runs between viable and non-viable tissue.

Water jet hydro surgery (Versajet®) has been described for burn wound excision, mainly in partial-thickness wounds.¹¹⁴ Authors cite precision and dermal preservation as the main benefits associated with this technique, with a randomized trial reporting equivalent adequacy of debridement and a shorter surgical time for the Versajet.¹¹⁵

Fascial excision involving surgical excision of the full thickness of the integument is reserved for deep burns extending down through the fat into muscle, late-presentation infected wounds and for failed initial surgery in patients with life-threatening invasive infections. It is undertaken with electrocautery and offers excellent control of blood loss, leaving a fascial wound bed which is an excellent for graft take. Unfortunately fascial excision is mutilating and leaves a permanent contour defect.

Avulsion can be used for conservatively treated deeper wounds. Physical removal of the necrotic eschar by avulsion from the underlying viable wound bed can be rapidly accomplished with minimal bleeding.

Primary amputation must be considered in the management of high-voltage electrical injuries or very deep thermal injuries with extensive muscle involvement and rhabdomyolysis which is life threatening. Limb salvage should always be attempted to preserve length and maximize function of the extremity. Amputation is reserved for patients who have an ischaemic limb or refractory invasive infection following repeated debridement. In other circumstances amputation is undertaken only if all other measures to preserve a useful functioning limb have failed.

Table 14.5 Estimated approximate blood loss given in millilitres per square centimetre burn excised in patients >30% TBSA burn

Day post injury	Estimated blood loss (mL/cm ²)
0–1	0.4
1–2	0.6
2–16	0.75
>16	0.5

Blood loss

Blood loss during burn surgery can be massive and the amount required can be estimated. Blood loss depends on timing of the surgery following injury and the area of wound that requires excision and autografting. To estimate blood requirements pre-operatively the burn size in square centimetres should be estimated. A calculation can then be made if the time post injury is known (Table 14.5).¹¹²

Blood and blood products must be ordered and present in the operating theatre prior to the commencement of surgery. Incorporating this into the World Health Organization patient safety checklist should minimize complications of blood loss.¹¹⁶

Blood loss during surgery can be minimized by the use of sterile limb tourniquets, infiltration of the eschar and donor sites with 1/10⁶ solution of adrenaline (1 mg in 1000 mL N saline) and warm topical phenylephrine (2% solution)-soaked dressings. It is possible to debride and excise significant wounds without the need for blood transfusion.

Operative approach and anatomical considerations

The sequence of wound excision and cover depends on surgeon and institutional preference. In large injuries the sequence usually is the posterior trunk, anterior trunk, lower limbs, upper limbs, and head and neck in order. This sequence maximizes the area covered with autograft early in the course of treatment and allows for early mobilization and ambulation. In general, sheet grafts should be used whenever possible. Care must be taken when mesh grafts are used as contracture can occur in the line of the interstices. Mesh graft interstices on the trunk and breast should be placed horizontally. Care should be taken to preserve the breast or breast bud, especially in females, and to place enough skin with minimal mesh expansion into the inframammary folds and the sternal area to try and reduce subsequent breast deformity. The umbilicus should be preserved if possible.

The buttocks are difficult to manage and skin graft take is poor. They are prone to faecal soiling and shearing and can be the site of repeated bouts of invasive wound sepsis. It is often

worth autografting them in the first operation, but graft take can be disappointing. If the grafts fail it is then best to leave the area for a time when the patient can be nursed prone while the grafts take. This is usually done after all other areas are healed. It is not usually necessary to perform a colostomy to prevent faecal soiling as the faecal stream can be diverted with a rectal tube. The perineum and genitalia are usually managed conservatively, with grafting of any unhealed areas later on in the course of surgical treatment.

Mesh graft interstices on the limbs should run longitudinally along the line of the limb except at the joints. At the knee, ankle, axilla, elbow and wrist joints graft expansion should be minimized if possible and the direction of the interstices should be the same as the axis of rotation of the joint (i.e. perpendicular to the longitudinal axis of the limb).

The skin on the sole of the foot is glabrous skin and is very thick and specialized. It will commonly re-epithelialize despite what initially seems a full-thickness injury. The sole of the foot is best treated conservatively until it is apparent that spontaneous re-epithelialization will not occur. In contrast, the skin on the dorsal aspect of the foot is very thin and often requires grafting. It is important not to use widely meshed skin in this area as any significant hypertrophic scarring can cause difficulties with weight-bearing ambulation and fitting of shoes.

The burned hand requires attention to detail to achieve optimal functional and cosmetic results. The volar aspect of the hand is covered with specialized glabrous skin, which usually heals and it is best to avoid grafting it if possible. The dorsal skin is thin and usually requires grafting in deep burns. In general, sheet graft is preferable to mesh graft and is best secured with absorbable sutures. Mesh interstices should run longitudinally along the hand and digits. The key to functional success is early mobilization of the hand. Initially after grafting the hand is dressed and splinted in the position of safety with the metacarpophalangeal joints flexed at 70–90°, the interphalangeal joints at 180°, the wrist in neutral or slightly extended and the thumb flexed and adducted at the metacarpophalangeal joint. The grafts are inspected at 5 days and, if stable, mobilization can be started. If sheet grafts are used they can be exposed with no dressing during mobilization during the day with splintage at night.

In patients with large burns, repeated application of allograft may be required until it is time to autograft the hands. It can be very difficult to maintain the position of safety of the hand during this phase and K-wires through the metacarpophalangeal and interphalangeal joints may be required to maintain the joints in optimal position.

Deeper burns of the face will often benefit from early excision and autografting. Medium to thick sheet split-skin autograft should be used for the face and applied in cosmetic units to place marginal scars in natural skin crease lines. If available, donor sites should be above the neck for optimum colour and texture match. The scalp is an excellent donor site for grafts destined for the face. The use of skin substitutes such as Integra® have been described as giving superior cosmetic outcomes.

Early excision and closure of eyelid burns reduces the incidence of corneal injury secondary to exposure and should be a priority. When applying autograft to the eyelids, thick split-thickness graft should be used and overcorrection should be performed, putting more skin in than seems to be needed as contraction can lead to corneal exposure.

Wound closure

Following wound excision it is vital to obtain wound closure to reduce invasive infection, evaporative water loss, heat loss and pain. Wound closure can be permanent using autologous split-skin graft and is considered the gold standard. Temporary physiological closure using allograft or skin substitutes allows time for donor site healing.

Although autologous split-skin grafts are considered the gold standard for resurfacing burns. Full-thickness grafts tend not to be used for acute burns and are usually reserved for postburn reconstruction.

Split-skin grafts have a more reliable 'take' and can be harvested either with a hand knife or with a powered dermatome. They can be used as sheet grafts or can be meshed using expansion ratios of 1:1, 2:1, 3:1, 4:1, 6:1 and 9:1. Other skin expansion techniques such as the Meek technique are also invaluable for covering large areas of wound.¹¹⁷

Allograft skin harvested from cadaveric donors is an essential skin substitute used in the management of extensive burns. Appropriate donor selection, screening for communicable disease, consent from relatives and strict exclusion criteria are applied to ensure safety for transplantation. These functions are undertaken in addition to screening, harvesting, processing and distribution by regional or national tissue banks. The amounts required can be estimated by determining the body surface area and burn size in square centimetres.¹¹⁸

Fresh viable allograft skin can also be obtained from living donors, usually parents or relatives of burned children, however in view of the good quality and quantity of allograft skin provided by tissue banks, this method is used infrequently.

Allograft skin is mainly used meshed 2:1, allowing haematoma and seroma drainage. Sheet allograft tends to be used to cover cosmetic areas such as the face as a temporary covering.^{119,120}

Acellular bilaminar skin replacements have been extensively used that provide wound closure with theoretical permanent dermal replacement. An upper silicone layer acts as a temporary epidermis, forming a barrier to microorganisms and controlling evaporative water loss. The deeper layer is a cross-linked bovine collagen and chondroitin-6-sulfate matrix. This matrix is vascularized and incorporated into the wound. It is termed a 'neodermis' and is used to replace dermis in full-thickness burns and modulate postburn hypertrophic scarring. These dermal replacements have produced encouraging results both in single-centre studies and in a multicentred randomized controlled trial. These studies have reported less hypertrophic scarring

with a pliable scar and a reduced requirement for secondary reconstructive procedures. Long-term studies describing benefit are lacking.¹²¹

More recently synchronous application of a dermal substitute and skin graft has been established as a standard procedure. This approach obviates the need for a second procedure for application of autograft. In a pilot study comparing simultaneous transplantation of a dermal substitute and split-thickness autograft or split-thickness autograft alone it was reported that simultaneous application of a dermal matrix was safe, feasible and gave significantly better results with respect to skin elasticity.¹²²

De-epidermalized decellularized sterile human dermis can be used as a dermal replacement for acute care and for postburn reconstruction. In acute cases, the burn wound is excised and prepared as usual. The de-epidermalized decellularized dermis is applied to the wound and a thin (epidermal) split-skin graft is applied over it. This bilayered graft is secured and managed as skin graft. This technique has limited applications in the management of large surface area acute burns due to paucity of skin graft donor sites. It is more been used more successfully in postburn reconstruction.¹²³

Amnion is commonly used by ophthalmologists to cover damaged corneas as it is immunologically privileged tissue, has antiangiogenic properties and contains many growth factors that stimulate epithelial proliferation. Amnion has been used in burn care mainly in partial-thickness wounds. The risk of disease transmission, limited availability, small size and fragility limit its usefulness in burn care.¹²⁴

A variety of xenograft materials (sheep skin, frog skin) have been used as a skin substitute, but the only commonly commercially available product is from domestic swine. It has been processed in a number of ways, including irradiation, lyophilization, glutaraldehyde cross-linking and impregnation with silver to reduce antigenicity and prolong adherence. Porcine xenograft is usually available as de-epidermalized dermis, which is essentially a collagen matrix. Porcine skin xenografts can reduce evaporative water loss, limit infection, and encourage autologous epidermal growth. They are useful as temporary coverings for partial-thickness burns, donor sites and desquamating skin conditions. They are easily available, have a prolonged shelf life and are relatively inexpensive.¹²⁵

Cultured epithelial autografts (CEAs) have been used by burn surgeons for over 20 years. From a 1 cm² autologous skin biopsy, tissue culture techniques in the laboratory can produce enough epidermal cells (keratinocytes) in approximately 3–4 weeks to cover an adult of up to 2 m² body surface area. There have been many reports of successful use of CEA to close burn wounds, however the technique only produces the epidermal layer for wound closure. The cost of production is significant, there is a lag time of three weeks from biopsy to production of adequate quantities, the take rates can be low, and the grafts are very fragile and shear easily and blister even after successful take, due to poor and delayed basement membrane formation. Grafting

the CEA on to an allograft dermal bed as described by Cuono in 1986 improves take and durability.¹²⁶

More recently the use of subconfluent, autologous keratinocyte suspensions sprayed onto excised wounds has been described to treat partial-thickness wounds and excised wounds. In addition, augmentation of epithelialization by spraying interstices of widely meshed skin grafts and also skin graft donor sites has been used. The use of CEA is reserved for patients with major or massive burns with limited donor sites or ones that are difficult to harvest and cosmetically and functionally important.¹²⁷

Donor sites

The splint skin graft donor site is an important and often neglected wound that is vital to the successful care of burn patients. Management of a donor site wound should promote re-epithelialization with a minimum pain and discomfort. In major injury where donor sites need to be reharvested, they become a precious commodity that requires meticulous care to optimize healing and minimize infection so that the donor site can be reharvested in the shortest time possible.

Initial management at the time of harvest will include the use of topical adrenaline to limit bleeding and infiltration of the wound with a long-acting local anaesthetic such as bupivacaine.

Many dressings are available for donor site care and the choice usually depends upon surgeon preference and availability. In general, donor site dressings will involve a primary contact layer such as Telfa™ Clear (polyethylene terephthalate), Mepitel (silicone) or Jelonet® (paraffin gauze) covered with an absorbable layer of gauze and wool secured with a crêpe bandage.

In a recent randomized controlled trial, moist wound healing provided by hydrocolloid dressings was associated with the shortest healing rates when compared to other dressings, including alginate, semipermeable film, gauze, hydrofibre and silicone. In the same trial, patients treated with a gauze dressing had a higher rate of infection.¹²⁸

Rehabilitation

Burn rehabilitation starts on admission to the burn service. Passive measures such as patient positioning, splintage and control of oedema maintain range of motion and function. Active mobilization and promoting functional activities should also be encouraged from the earliest time possible.¹²⁹ Respiratory care and rehabilitation to maintain spontaneous ventilation, cough and expectoration minimize the need for mechanical ventilation and its associated complications.

Consistent repetitive motivational education is a vital part of patient care, with patients being encouraged to share responsibility to optimize their rehabilitative opportunities. Well-motivated

patients can surpass expectations with regard to functional recovery, whereas poorly motivated patients can end up with poor functional outcomes despite best efforts. Early exercise has been shown to be beneficial following paediatric burn injury, enhancing lean body mass and strength, without exacerbating postburn hypermetabolism; however the evidence for this is still lacking in an adult population.¹³⁰

Scar management

Hypertrophic scarring is a common problem following burn injury, with a high incidence in those wounds that take longer than three weeks to heal. They are typically thick, red and raised and can be symptomatic in terms of pain and itching. The hypertrophic scar is thought to result from an overproduction of collagen and an imbalance between the anabolic and catabolic phases of healing. Hypertrophic scarring causes significant aesthetic, functional and psychosocial morbidity and takes 18–24 months to mature.¹³¹

These scars require lifelong care, including moisturizing with creams and sun protection. Sun exposure causes hyperpigmentation, but there is no evidence of an increased risk of developing skin cancer.¹³² Scar maturation can be modulated by scar massage, pressure and the use of topical silicone.¹³¹ Custom-made pressure garments are used but are expensive. Recommendations include the use of continuous pressure of 15–40 mmHg, applied for at least 23 h/day for more than six months.¹³³ However, compression therapy is limited by the ability to adequately fit the garment to the wounded area, and patient discomfort frequently reduces compliance. There is little evidence of efficacy compared to simple elasticated bandages.¹³⁴

Silicone gel sheeting is thought to decrease collagen remodeling and hasten scar maturation, although the exact mechanism of action is unclear and the evidence is not strong.¹³⁵ Side effects of silicone sheeting include local skin reactions, such as maceration and pruritus.

Scar management is usually undertaken and supervised by physical therapists on a regular three-monthly basis in an outpatient clinic in association with the surgical team.

Psychological support

Psychological support of the burn patient is vital and must be a routine part of treatment from the outset of care. Depression and posttraumatic stress disorder (PTSD) are the most common psychological problems and are often linked to preinjury morbidity. Other risk factors include pain, anxiety, female gender and facial scarring. Therapeutic interventions include optimizing social functioning and adjustment as well as therapies directed toward anxiety, depression and PTSD.¹³⁶

Return to work can be considered as one of the ultimate goals of postburn rehabilitation, demonstrating reintegration into society. In a retrospective review 90% of patients returned to

work at 24 months post injury. Only 37% returned to the same job. Predictors of return to work outcome included TBSA, anatomical site of injury, length of hospital stay, preinjury personality and psychiatric morbidity and demographic factors including preinjury employment status.¹³⁷

Burn reconstruction

The aim of postburn reconstruction is to preserve, restore and improve function, comfort and appearance. This requires an organized approach with functional issues taking precedence over aesthetic concerns. Normal and hypertrophic scarring, scar contracture, loss of parts of the body, and change in colour and texture of injured skin are processes common to all burned patients.

Prevention of dysfunction and deformity starts on admission and carries on throughout the acute injury phase. Once wound healing has been achieved, patients go into scar management programmes consisting of the use of pressure garments, massage and moisturizing therapy to optimize scar maturation.

Timing

Surgical reconstruction is usually delayed until scar maturation has occurred and the effects of scar management are well established after about 12 months. As unsightly scars mature over time they become flexible and pliable, and patience on the behalf of both surgeon and patient is recommended.

Timing of reconstruction is guided by the clinical scenario and can be categorized as urgent (immediate), essential (early) or desirable (late). Urgent (immediate) procedures are indicated for problems such as cover for exposed vital structures or to preserve function in vital areas and should be performed after all open wounds are closed. Examples include release of eyelids to protect the cornea, microstomia, entrapment of neurovascular bundles and severe neck contractures.

Essential (early) procedures are performed to improve rehabilitation and function, and usually for mature burn scar contractures that do not respond to splinting or aggressive physical therapy. Examples include neck contractures, joint contractures (e.g. elbow, knee and ankle), mobility-limiting contractures (e.g. axilla, groin) and hand contractures.

Desirable (late) procedures encompass the majority of reconstructions and are performed after the scar has matured and address the size and shape of the mature scar, including abnormalities in colour and texture with the aim of producing the best aesthetic result possible. Examples of late reconstruction include reconstruction of passive areas (e.g. trunk, extremities) and aesthetics (e.g. face, breast).

Following any reconstructive procedure, occupational and physical therapy, scar management and skin care are all essential to postoperative management to ensure optimal outcome.

A realistic approach is necessary to counsel patients' expectations to the probable outcomes of reconstructive surgery and a good patient–surgeon relationship is essential.¹³⁸

Planning reconstruction

Surgical planning should be undertaken following a thorough review of the problems and potential solutions and should include a record of the acute care, a full history and physical examination, a record of problems noting quality and colour of the skin, scars, pigmentation, contractures, atrophy and open wounds. A functional assessment should be made and recorded with the aid of the physiotherapists and occupational therapist, including the contribution of both soft tissue and skeletal deformity. A full donor site inventory should be made so that they can be prioritized according to the patient's reconstructive needs.¹³⁸ Different anatomical and functional sites require different reconstructive options, including skin grafts, skin substitutes, tissue expansion, local, regional and distal flaps.

Outcome

Measurement of outcome in burns patients is complex and multifaceted. As increased numbers of burned injured patients survive, a more comprehensive assessment of outcome deserves high priority.

Mortality and length of stay have traditionally been used as outcome measures, although crude mortality data are not helpful due to lack of risk stratification. The percent TBSA burn at which half of patients admitted to the burns unit die calculated by probit analysis of mortality data is known as the lethal dose 50% (LD%) and is the standard mortality outcome that can be used to compare services.¹³⁹ Length of stay is a good global surrogate measure for outcome and quality of care reflecting the whole patient journey, including assessment, admission, fluid resuscitation, surgical care, nutrition, critical care, physical and psychosocial rehabilitation. Delays in discharge reflect complex rehabilitation, psychological or social issues.

More complex outcome analysis has been proposed that encompasses a wider range of domains, including skin, neuromuscular function, sensory function, pain, psychological function, physical function, community participation and perceived quality of life. The optimal measurement tools of these outcome domains are yet to be fully developed.¹⁴⁰

The future

Prevention should be the ultimate global goal of burn care to reduce the burden of disease, disfigurement and disability. Future advances will concentrate on modelling care to suit a patient's individual genetic makeup and response to tissue injury and trauma.

The application of regenerative medicine techniques both in the acute setting and subsequent rehabilitation and reconstruction will be individually tailored to match bespoke patient needs.¹⁴¹ Tissue engineering holds great promise for all reconstructive surgeons. The combination of regenerative medicine and tissue engineering will allow prefabrication of flaps with specific characteristics, and the availability of 'off the shelf' skin and soft tissue constructs.

Tissue allotransplantation holds great promise in areas of complex 3D reconstruction, such as the face; however, the issues associated with immunosuppressive therapy and its complications must be addressed.¹⁴²

³Department of Plastic Surgery, Great Ormond Street Hospital for Children, London, UK

Incidence of phenotypic classification

Congenital melanocytic naevi (CMN) are present at birth, or very occasionally, arise in the first 2 years of life (*tardive CMN*). These lesions grow commensurate with the child, but tardive lesions can appear to grow more rapidly as the full extent of the CMN is often not initially apparent. The incidence ranges from 1 to 2% if all sizes are considered to approximately 1 in 20 000 for naevi projected to be greater than 20 cm in diameter in adulthood.¹ CMN are commonly classified according to maximum projected adult size and the total number of lesions at birth. The most recently proposed classification of size is small (CMN with an estimated diameter in adulthood of less than 1.5 cm), medium (M1, 1.5–10 cm and M2, 10–20 cm), large (L1, 20–30 cm, L2, 30–40 cm) and giant (G1, 40–60 cm, G2, >60 cm).² However, the authors prefer not to employ the term *giant* as it is often unacceptable to patients and families.

The estimates of projected adult size are determined in a variety of ways, none of which are decidedly accurate, but remain the most reliable methods currently available. Some clinicians use a scaling factor applied to the CMN diameter at birth. More specifically, a CMN on the head is predicted to enlarge by a factor of 1.7, on the trunk and upper extremity by a factor of 2.8 and on the lower extremity by a factor of 3.3.³ This approach is not without fault, as CMN often affect more than one region of the body and it does not account for significant differences in growth between the sexes. Other clinicians therefore estimate the projected adult size by drawing the child's CMN onto an adult body map, and estimating the longest non-circumferential diameter.

CMN can present as isolated singular lesions or can be accompanied by a variable number of smaller discrete so-called *satellite* lesions. These lesions should be counted or estimated as each satellite lesion represents an additional CMN.

Histological and clinical appearances of CMN

CMN consist of nests of naevus cells, which differ from normal melanocytes in their non-dendritic morphology and proclivity to form nests. Melanocytic nests are present at the dermo-epidermal

junction, within the dermis and/or subcutaneous tissue, and naevus cells can be localized between collagen bundles and found surrounding dermal appendages, blood vessels and nerves. Small and medium-sized CMN generally present clinically as homogeneous pigmented lesions with well-delineated borders, an increase in skin surface markings and variable hypertrichosis. Larger CMN express colour variegation, are often asymmetric with irregular borders, can have a nodular surface and are usually hypertrichotic (Figure 15.1).

Nodules are often appreciated to arise within the substance of the CMN or can be present at birth. Any such focal change within a CMN should be viewed with suspicion and reviewed by a paediatric dermatologist. Although malignancy should always be considered, the vast majority of nodules are benign and repeated excisions can thus be avoided. Histopathology and genetic investigations can assist in differentiating between benign proliferative nodules and melanoma, in particular array comparative genomic hybridization.⁴

Neurological associations of CMN

Individuals with CMN can be divided into those with a cutaneous phenotype only (either single or multiple), and those with extracutaneous features (either neurological or facial), the latter then termed *congenital melanocytic naevus (CMN) syndrome*. The projected adult size of the lesion, as well as the total number of CMN at birth is known to be associated with adverse clinical outcomes. Neurological abnormalities are the most common complication of CMN, and this association has previously been known as *neurocutaneous melanosis*. The latter term has now been supplanted by *CMN syndrome*, as the neurological complications are not always melanotic in nature. The prevalence of neurological abnormalities increases with the size of the largest CMN and the total number of naevi.^{5,6} CMN distribution, in particular, lesions on the posterior axis, is not associated with an increased risk of neurological anomalies. The previously suggested connection between cutaneous distribution and neurological risk

Figure 15.1 Clinical images of different cutaneous phenotypes of CMN.

was confounded by the fact that the largest lesions are often located on the back.

The most common neurological complication is intraparenchymal melanosis, where foci of melanin-producing cells are found within the brain parenchyma, most notably in the amygdala.⁷ Intra-parenchymal melanosis without other neurological abnormalities on MRI are benign congenital lesions and entirely asymptomatic in approximately half of cases. The other half of cases can exhibit developmental delay. Although delay is most frequently mild, global developmental retardation or behavioural problems, such as attention deficit hyperactivity disorder or autistic spectrum disorder, can be present.⁶ Even when symptomatic, these lesions are not a sign of malignancy or of impending death, and should not be considered for surgical resection. Although rare, progression to malignant melanoma remains a possibility. However, the latter can arise in the CNS even in the absence of visible intraparenchymal melanosis.

Other congenital neurological anomalies such as Dandy–Walker malformation, hydrocephalus and brain or spinal cord tumours can occur, with or without leptomeningeal melanosis. These more complex neurological abnormalities are much more commonly symptomatic with manifestation of seizures and developmental delay, and therefore necessitate more rigorous management, with regular MRI, neurological assessments and frequently, neurosurgical consultation.⁸ Interestingly, it has been shown that neurological symptoms in patients with CMN can be present in the absence of any perceptible radiological abnormality.^{6,9} This finding has been proposed to be related to lesions that cannot be visualized with current imaging techniques.¹⁰ Thus, the authors' current management protocol includes a gadolinium-enhanced MRI of the CNS for any child

with the onset of abnormal neurological signs or symptoms at any age (irrespective of a previously normal scan) and routinely for *all children with two or more CMN at birth, independent of size or site* (Figure 15.2).

Follow-up of children with CMN or CMN syndrome depends on the severity of the cutaneous phenotype, the neurological presentation and the risk of melanoma. Patients should have access to a specialist paediatric dermatology clinic with input from a multidisciplinary team including paediatric plastic surgeon, neuroradiologist, neurologist, neurosurgeon, psychologist and oncologist when necessary.

Malignant melanoma and CMN

Primary malignant melanoma of the skin or CNS is a rare complication of CMN. However, the incidence varies with the severity of the cutaneous phenotype. The cited estimates of the incidence of malignancy have been extremely variable, ranging from 0 to 40%. More recent and reliable data on the incidence of malignant melanoma and the clinical phenotype of CMN associated with its development have been published. Large studies have demonstrated that although there is an increased risk of melanoma in patients with CMN (especially during childhood and adolescence), it is in fact much lower than previously reported estimates, with the overall incidence for all sizes of CMN between 0.7 and 2.4%.^{11–13} However, the risk of melanoma increases with CMN of projected adult size >40 cm and satellite lesions at birth. Although the incidence of malignant transformation in this group has to be definitively elucidated, a recent prospective study

Figure 15.2 Protocol for management of CMN in childhood. PAS, projected adult size.

suggested an estimated incidence of 14% in those with CMN of projected adult size of >60 cm or multiple naevi.¹¹ Authors therefore proposed that patients with CMN of <20 cm projected adult size without satellite lesions at birth should be reassured that the risk of melanoma, at least in childhood, is approximately 1%. When melanoma does arise in these children, it is usually highly aggressive, refractory to therapy and rapidly fatal.^{11,12} The median age of onset is estimated at 7 years.¹²

Genetics of CMN

The causative genetics of multiple cutaneous CMN and CMN syndrome have recently been elucidated. These are engendered by somatic mosaicism for mutations in the gene *NRAS*,¹⁴ and are therefore one of the mosaic RASopathies (genetic disorders of the RAS/MAPK pathway).¹⁵ *NRAS* is a known oncogene involved at the somatic level in the development of melanoma, and although mutations in a variety of oncogenes have been described in individual CMN,^{16–18} no causal association between these findings has previously been made or suggested for the multisystem disorder. Developmental *NRAS* mutations predispose to melanoma in individuals with CMN syndrome by acting as the first insult in the subsequent occurrence of melanoma.¹⁴

Evidence is suggestive, however, of a germline predisposition for the development of CMN, with a higher prevalence

of smaller CMN in family members of affected individuals,^{11,14} as well as rare reports of large CMN in first-degree family members.^{19,20} In one UK study, homozygosity and compound heterozygosity of variants in the *melanocortin-1-receptor* (*MC1R*) gene were found at a higher prevalence in individuals with CMN and certain variants were associated with a more severe cutaneous phenotype.²¹ The *MC1R* is a G-protein coupled receptor expressed on melanocytes, melanoma cells and CMN cells. The *MC1R* gene is responsible for red hair and freckling in humans. Kinsler *et al.*²¹ proposed that the *MC1R* gene is implicated in the pathogenesis of CMN syndrome, based on the observation of a high prevalence of red hair pigmentary phenotype in families of children with CMN. More specifically, certain *MC1R* variants appear to promote growth of CMN during embryogenesis. *MC1R* variants are a risk factor for melanoma development in the general population and may contribute to the increased risk of melanoma in individuals with CMN. The lifetime risk for melanoma is approximately 1–2% when all CMN are considered together as a group, which is comparable in magnitude to the excess risk associated with *MC1R* variants in the normal population.

Recently, characteristic facies in children with CMN has expanded the description of this condition (Figure 15.3). Typical features include a wide or prominent forehead, apparent hypertelorism, eyebrow variants, periorbital fullness, small/short nose, narrow nasal bridge, anteverted nares, broad nasal tip,

Figure 15.3 Facial appearances of children with CMN.

Table 15.1 Prevalence of characteristic facial features of children with CMN

Facial feature	Prevalence (%)
Wide or prominent forehead	74
Apparent hypertelorism	12
Eyebrow variants	36
Periorbital fullness	27
Small/short nose	25
Narrow nasal ridge	18
Flaring nares	15
Broad nasal tip	34
Broad or round face	71
Full cheeks	55
Prominent premaxilla	10
Prominent everted lower lip	47
Prominent or long philtrum	20

The presence of three or more features is required to fulfil the facial criteria for congenital melanocytic naevus syndrome.

broad or round face, full cheeks, prominent premaxilla, open mouth appearance, everted lower lip, and prominent or long philtrum.²² (Table 15.1). In support of the notion that children with CMN display a distinctive facies is the fact that aberration in neural crest development gives rise to melanocytic and facial development in humans. Indeed, a single genetic abnormality may be responsible for CMN, neurological abnormalities and the characteristic facies of these children, by affecting the pluripotent cephalic neural crest cells that ultimately differentiate into diverse cell types including melanocytes, neurons, glia, osteocytes and chondrocytes. The genes on the RAS/MAPK pathway are known to be involved in facial development, and individuals with germline RASopathies have characteristic facies. This clinical finding is therefore consistent with *NRAS* mosaicism affecting neural crest or neuro-ectodermal structures, including pigment cells, cells of the CNS as well as bone and cartilage of the face.

Thus, the term *congenital melanocytic naevus syndrome* has been proposed with preliminary diagnostic criteria in an effort to formally characterize and unite these aspects of the condition. The following two criteria are included, both of which must be present. First, the presence of a CMN of greater than 5 cm projected adult size or more than one CMN of any size at birth. Second, neurological involvement (clinical or radiological) and/or the presence of three or more typical facial features.

Surgical management of CMN

Irrespective of size, long-standing practice for treatment of CMN has been surgical removal. A commonly cited argument in favour of early surgical excision is to decrease or avert the potential for malignant degeneration to melanoma. However, *surgical excision has not been shown to reduce the risk of malignant melanoma formation in patients with CMN*. First, individuals at high risk for malignancy have very extensive CMN associated with numerous smaller CMN, which can total in excess of 400 CMN. *Complete* excision of a very large CMN and *all smaller naevi* remains an impossibility (Figure 15.4). Second, there is some evidence that the behaviour of naevus cells may in fact be altered by surgical intervention. In a recent study,²³ tissue expansion was associated with the development of new naevi, supported by individual case evidence from other centres (Taieb A, personal communication). The latter is thought to occur secondary to either non-naevus cell melanocytes that are activated by some aspect of treatment with tissue expanders or that treatment promotes the spread of naevus cells from the primary naevus, a type of benign metastasis known to occur in CMN and Spitz naevi. Moreover, an increased incidence of darkening of surgically treated areas of CMN and untreated areas of partially excised CMN were noted, and new CMN were found to appear at the edge of the treated area.²⁴ An additional important consideration is that the occurrence of *malignant*

Figure 15.4 Child with a giant CMN and multiple smaller CMN, demonstrating the surgical impossibility of eradicating all lesions.

melanoma is not restricted to the CMN, and thus surgical excision of the primary CMN does not preclude development of melanoma in the CNS or other extracutaneous locations.

CMN can be aesthetically displeasing and as such associated with considerable psychological morbidity. Thus, a secondary argument for surgical excision of CMN is aesthetic concerns. However, there is evidence that untreated CMN often lighten over a period of years (Figure 15.5). Thus, with the exception of tardive CMN, the colour of CMN is darkest at birth. Although this phenomenon is quite variable, and the degree of depigmentation cannot be reliably predicted, the authors recommend observation with serial photographs for at least a year to assess for spontaneous lightening. Of note, scalp CMN appear to reliably display the most considerable amount of change. The latter is further supported by a recent series of spontaneous involution of scalp CMN in childhood.²⁵ Thus, removal of scalp lesions by tissue expansion is no longer advised, given the significant surgical intervention required and notable associated complication rate (e.g. alopecia). Often, however, these lesions extend into neighbouring areas of face, which can be addressed surgically (Figure 15.6). In fact, facial lesions, whether the primary CMN or a satellite lesion, are in the authors' practice routinely excised, as are CMN that can be completely removed by staged serial excision (Figure 15.7). Operative management is also routinely offered to patients with functionally troublesome or particularly prominent areas (e.g. large nodule) or areas suspect for malignancy. Clinical surveillance of CMN remains the principal treatment option for large or giant CMN or those in areas where excision would result in significant anatomic or functional compromise.

Earlier treatment modalities utilized in the surgical management of these lesions included curettage and dermabra-

sion. More recently, laser therapy has been introduced as an additional therapeutic option. One premise for these options has been the suggestion that superficial naevus cells bear the most malignant potential and therefore removal of these cells will effectively reduce the risk.²⁶ However, it is well documented that malignant transformation within CMN most often occurs within the deeper cells of the dermis and subcutaneous tissue.²⁷ Indeed, two thirds of cutaneous melanoma within CMN develops below the dermo-epidermal junction. Thus, the effects of superficial excision can mask the appearance of a melanoma arising within the CMN. Moreover, these techniques are associated with significant morbidity including bleeding, infection (sepsis), scarring and recurrent folliculitis. Most importantly, all lesions treated with superficial removal re-pigment over time, at variable rates ranging from weeks to years. Large CMN extend through the entire dermis, often into subcutaneous tissue. Initially, after elimination of superficial naevus, there is a noticeable decrease in pigmentation, as the deeper naevus cells do not produce melanin. However, once these deeper cells become more superficial they begin to produce melanin, resulting in re-pigmentation (Figure 15.8). Comparison of the colour of re-pigmented CMN following superficial removal is intrinsically biased, as CMN spontaneously lighten over time. The latter is evident when treated and untreated areas in the same individual are compared, where no difference in pigmentation is observed.

Currently, the primary methods in the operative management of CMN include single-stage excision with primary closure, staged serial excision, tissue expansion and excision with either partial- or full-thickness skin grafting. Any of the aforementioned techniques can be used alone or in combination, following consideration of the aesthetic unit(s) to be addressed. Although implemented by some clinicians, free or pedicled flap

Figure 15.5 Spontaneous lightening and regression of an untreated CMN. In this case, lightening became evident after 6 months of age. Illustrated are images of the CMN at age (a) 2 months, (b) 1 year, (c) 2 years and (d) 3 years. Of note, the last image demonstrates CMN regression in addition to depigmentation.

Figure 15.6 (a) Child with a large CMN involving the scalp, forehead, temporal region and lateral aspect of the cheek and ear. In this case, only the part of the CMN on the face was surgically excised. The resultant defect was resurfaced with a split-thickness skin graft harvested from the scalp. (b) Result at 6 months following the procedure.

Figure 15.7 Child with a giant CMN and multiple smaller CMN. In contrast to the child in Figure 15.4, this patient would be offered the possibility of excising the two smaller CMN on his face, which are harbingers of the larger so-called *bathing suit pattern* CMN.

Figure 15.8 CMN treated with superficial excision demonstrating re-pigmentation. (a, b) CMN at day 1 of life. (c, d) CMN 2 months following dermabrasion. (e, f) CMN 2 years following dermabrasion, which shows the return of pigment to all treated areas.

coverage (with or without tissue expansion) in an effort to eradicate large or giant CMN is not considered in the authors' surgical armamentarium, given the previously stated points and in view of the considerable morbidity associated with these interventions. In general, unless there is a specific concern with regards to malignancy or functional issue, surgery is delayed until after 2 years of age. Occasionally, however, partial or complete excision with primary closure is effected earlier taking advantage of the skin laxity in infancy. It is important that the full thickness of the lesion be excised, and thus carried down to the subcutaneous tissue layer.

In cases where excision and primary closure is not a practicable alternative, serial excision is considered if complete excision can be accomplished in two or three stages. In cases where closure with skin graft is planned, usually for CMN of the face or hand, either a split- or full-thickness skin graft is selected based on size and location of the excised lesion. For large areas where full-thickness skin graft coverage is planned, pre-expansion of the donor skin prior to harvest minimizes the aesthetic morbidity at the donor site. As previously mentioned, in the authors' practice, facial lesions are routinely excised, sparing areas of naevi involving delicate facial structures that remain difficult to reconstruct without significant risk of iatrogenic deformity (e.g. alar rim, hair-bearing eyebrow). For facial lesions, where a split-thickness skin graft is selected, the scalp remains the donor site of choice. Full-thickness skin grafts are usually harvested from the post-auricular area or supraclavicular fossa (with or without pre-expansion of the area) depending on the size of the resulting defect. Tissue expansion of the area adjoining the CMN to be excised is generally avoided in the forehead. The latter usually does not give a superior aesthetic result to skin grafting and is associated with considerable risk for distortion of forehead musculature and unaffected neighbouring cosmetic units (namely, the eyebrow and hairline).

Conclusion

CMN can be restricted to the skin or associated with neurological abnormalities and/or characteristic facial features (CMN syndrome). Management of children with multiple (>1) CMN or CMN syndrome necessitates a multidisciplinary approach involving the care of a paediatrician, dermatologist, plastic surgeon, neurologist, neuroradiologist, psychologist and primary care physician. Children with more than one CMN at birth (irrespective of size or site) should have an MRI of the CNS and undergo routine neurodevelopmental assessment. Routine surgery with current techniques has not been shown to decrease the risk of malignancy in CMN. Moreover, there is no proven benefit to early intervention and some evidence suggests that surgery may adversely affect the behaviour of CMN cells. Based on these findings, a shift in management of these patients is recommended. In our current practice, surgery is delayed for

at least the first year, with serial photographs taken at yearly intervals to assess spontaneous lightening. Surgical intervention is offered to patients with CMN that are easily amenable to excision or those in aesthetically sensitive areas.

⁴Department of Plastic Surgery, Great Ormond Street Hospital for Children, London, UK

Vascular anomalies are disorders of the endothelium, which can be subclassified into vascular tumours and vascular malformations, distinguished by proliferating endothelium and quiescent endothelium, respectively¹ (Table 16.1). Vascular anomalies can affect individuals of any age and patients present to clinicians in a variety of clinical specialties. These lesions often require significant diagnostic expertise and a multidisciplinary management approach. Arguably, in no area of paediatric medicine is incorrect terminology more pervasive than in the field of vascular anomalies. This is largely due to insufficient training in the subject, the wide variety of terms and labels used in the historic literature and the involvement of many different medical specialties, each with their particular interests and assumptions. Correct designation using the standardized classifications and terminology introduced by the International Society for the Study of Vascular Anomalies (ISSVA) is paramount for appropriate patient management.² In the majority of cases, the precise diagnosis can be realized by detailed history and physical examination. In instances where diagnostic ambiguity persists, imaging proves useful, with ultrasound sufficient in most instances. Rarely, is tissue biopsy required.

Vascular tumours

The term *vascular tumour* encompasses a wide range of pathology, including common haemangiomas and other rare lesions such as tufted angiomas and kaposiform haemangioendotheliomas. The majority of *vascular tumours* have a rapid proliferative growth pattern and are composed of solid tissue, forming focal soft tissue masses. In contrast, *vascular malformations* are made up of vascular channels or cysts and are usually more diffuse. The most common vascular tumour is the *haemangioma*. Haemangiomas can be divided into infantile and congenital tumours. Infantile haemangiomas occur in approximately 3–10% of infants, and in up to 30% of premature infants. These lesions are most common in white infants, with a lower frequency in infants of African or Asian descent, and are 3- to 5-fold more

common in females than males.³ In approximately 20% of infants, multiple haemangiomas may be present, with five or more tumours termed *haemangiomatosis*. When five or more infantile haemangiomas are noted, further investigation with abdominal ultrasound is mandatory to exclude the presence of haemangioma in the liver. A rare presentation is *miliary haemangiomatosis*, in which a large number of small cutaneous haemangiomas, usually exceeding 20, are apparent soon after birth and recognized to be associated with internal lesions.

Infantile haemangiomas appear to arise from vasculogenesis, and more specifically, from multipotent derived stem cells, which have the potential to differentiate into multiple cell lineages and form human *glucose transporter isoform 1 (GLUT1)*-positive microvessels in immunodeficient mice.⁴ During the proliferative phase, these cells produce vascular endothelial growth factor, an endothelial mitogen. Indeed, *GLUT1* is uniquely expressed on the endothelial cells of haemangiomas and provides a valuable marker for differentiation of haemangiomas from other vascular tumours and vascular malformations. Haemangiomas have a characteristic evolution, appearing within the first few weeks of life, proliferating for several weeks to months, stabilizing between 6 and 12 months of age, and finally gradually regressing over a period of several years.

At birth, the site of the future haemangioma is usually completely normal, with the median age of appearance at 2 weeks. However in approximately 30% of cases, a nascent lesion may be present, such as an area of telangiectasia or pallor. Rapid growth then ensues, with tumours attaining approximately 80% of their maximal size by 3 months. After 12 months of age, the tumour usually begins the involuting phase. Classically, this stage is characterized by complete resolution of approximately 50% of lesions by 5 years of age, 70% by 7 years of age and 90% by 9 years of age (estimates derived from the study of Bowers *et al.*⁵). However, more recent clinical and histological work has demonstrated that involution is usually complete by age 4 years.⁶ Following regression, infantile haemangiomas can often leave residual telangiectasia, anetodermic cutaneous excess, fibro-fatty residuum, scarring and, rarely, significant structural deformity (Figure 16.1).

Table 16.1 Current classification of vascular anomalies

Tumours	Malformations	
	Slow flow	Fast flow
Infantile haemangioma (IH)	Capillary malformation (CM) Cutis marmorata telangiectatica congenita (CMTTC) Telangiectasias	Arterial malformation (AM) Aneurysm Atresia Ectasia Stenosis
Congenital haemangioma (CH)	Lymphatic malformation (LM)	Arteriovenous malformation (AVM)
Rapidly involuting congenital haemangioma (RICH)	Microcystic	Capillary malformation–arteriovenous malformation (CM-AVM)
Non-involuting congenital haemangioma (NICH)	Macrocystic Primary lymphoedema	Hereditary haemorrhagic telangiectasia (HHT) PTEN-associated vascular anomaly (PTEN-AVA)
Haemangioendotheliomas	Venous malformation (VM)	Combined malformations
Kaposiform haemangioendothelioma (KHE)	Cerebral cavernous malformation (CCM)	Capillary–arteriovenous malformation (CAVM)
Other	Cutaneomucosal venous malformation (CMVM) Glomuvenous malformation (GVM) Verrucous haemangioma (VH)	Capillary–lymphatic arteriovenous malformation (CLAVM)
Pyogenic granuloma (PG)	Combined malformations Capillary–venous malformation (CVM) Capillary–lymphatic malformation (CLM) Capillary–lymphatic–venous malformation (CLVM) Lymphatic–venous malformation (LVM)	

Source: Greene, 2012.²

The majority of haemangiomas are small and do not encroach onto anatomically sensitive areas, and as such, are clinically insignificant. These lesions are readily diagnosed in view of their characteristic appearance, including distinctive cherry-red colour. Occasionally, deep-seated tumours, which do not alter the colour of overlying skin are encountered, often requiring ultrasound to confirm the diagnosis. With these haemangiomas, families should simply be reassured that the tumour(s) will resolve with time and the lesion(s) followed only if there is cause for concern. Although infantile haemangiomas predictably undergo spontaneous involution, during their proliferative phase, they occasionally cause disfigurement and serious complications, including airway obstruction (subglottic haemangioma) or amblyopia (periorbital or orbital haemangioma), cardiac failure and/or hypothyroidism (hepatic haemangioma), ulceration and bleeding.⁷ In the past, such lesions were treated with corticosteroids or laser therapy.⁸ In 2008, Léauté-Labrèze *et al.*⁹ published a landmark paper where the unanticipated antiproliferative effect of propranolol on infantile haemangiomas was described. Propranolol has since proven to be highly effective and generally well tolerated,¹⁰ and is now the systemic treatment of choice.¹¹ The therapeutic action of propranolol is secondary to vasoconstriction, inhibition of angiogenesis and induction of apoptosis. Prior to initiation of propranolol, infants should be hospitalized for monitoring of any adverse effects, which have been reported to include bronchospasm, bradycardia, hypotension, hypoglycaemia, seizures, hyperkalaemia and diarrhoea. Evaluation with a baseline electrocardiogram and/or echocardiogram, vital

signs, blood glucose and electrolyte measurements are recommended. A history of asthma, blood glucose abnormalities and congenital heart disease are considered contraindications for initiation of propranolol therapy. For small superficial haemangiomas, early use of the topical beta-blocking agent timolol can be effective. The use of systemic corticosteroids is now reserved only as a second-line treatment, when propranolol is contraindicated.¹² There is no role for vincristine or interferon previously documented in the literature.

The use of pulsed dye laser should be reserved for treatment of residual telangiectasias following tumour involution. Surgical excision is commonly performed for tumours that are in the involuting phase. This is considered when it is evident that surgical intervention will be necessary and the resultant aesthetic outcome is predicted to be comparable to that anticipated during the involuted phase. Otherwise, resection is delayed until involution is complete. Serial excision or circular excision and purse-string closure can be utilized for surgical resection.¹³ Occasionally, excision can be considered in the proliferative phase, if for instance, outcome would be comparable to surgery effected later or if medical management is contraindicated or has failed.

Infantile haemangiomas can also occur in extracutaneous areas, most frequently in the liver. Internal organ involvement is more common in infants with multiple haemangiomas (>5) and haemangiomatosis. These hepatic tumours can instigate hepatomegaly, cardiac failure and/or hypothyroidism. The presence of a flat segmental facial haemangioma should prompt consideration

Figure 16.1 (a) Haemangioma of the left cheek, lower eyelid, lateral nose and upper lip in an infant. (b, c, d, e) Series of images at ages 3, 4, 5 and 10 years, which illustrate the natural regression of the haemangioma and resolution of the associated anatomic distortion.

of the associated diagnosis of 'PHACES' (the term PHACES comprises posterior fossa brain malformation, *haemangioma*, arterial cerebrovascular anomalies (most common associated finding), coarctation of the aorta and cardiac defects, *eye/endocrine* abnormalities and sternal clefting or supra-umbilical raphe).¹⁴ Evaluation of the brain and cerebral vasculature with MRI is important, although deciding which infants to image remains unclear. Similarly, segmental haemangiomas in the lumbrosacral region and perineum can be associated with ventral-caudal malformations, including omphalocele, imperforate anus, vaginal

and renal anomalies. Radiological investigation (ultrasound and/or MRI) is essential to exclude any associated abnormalities.

In contrast to infantile haemangiomas, congenital haemangiomas are almost always completely developed at birth and divided into *rapidly involuting congenital haemangiomas* (RICH) and *non-involuting congenital haemangiomas* (NICH), depending on their pattern of involution. Mulliken and Enjolras¹⁵ have characterized the disparate growth curves for congenital compared with infantile haemangiomas (Figure 16.2). Aside from the distinctive clinical presentation of these congenital lesions, as well as differing clinical

Figure 16.2 Growth curves for rapidly involuting congenital haemangiomas (RICH), non-involuting congenital haemangiomas (NICH) and infantile haemangioma (IH). Source: Mulliken and Enjolras.¹⁵ Reproduced with permission of Elsevier.

course, *negative GLUT1 immunohistochemical staining* is an important characteristic to distinguish congenital tumours from their infantile counterparts. There are no distinctive imaging features that reliably differentiate between a RICH and a NICH, with both types appearing as well-defined, hypervascular, relatively homogeneous masses on ultrasound.

For some RICH, involution may begin within the first week of life. In most infants with RICH, regression is complete within the first 7–14 months of life, with anetodermic cutaneous excess remaining. Interestingly, in a small proportion of patients with RICH, involution may be incomplete, resulting in a residuum clinically indistinguishable from NICH. A typical NICH forms a flat violaceous vascular plaque with coarse surface telangiectasia bordered by a blue-white rim. Unlike their infantile counterparts, congenital haemangiomas rarely require intervention in infancy. Given the clinical course of RICH, observation is the mainstay of treatment. Occasionally, very large RICH may incite congestive heart failure due to their hypervascularity, in which case embolization is considered to dampen the lesion's arterial supply until regression has commenced. The latter is particularly common with hepatic RICH.

Aside from their clinical behaviour, hepatic RICH are typically unifocal, and are therefore readily distinguished from hepatic infantile haemangiomas, which are multifocal and usually clinically silent. Large RICH may also result in localized deformity requiring surgical intervention in later childhood. More specifically, these lesions may cause *fat atrophy* resulting in contour deformity (in contradistinction to infantile haemangiomas, which often leave fibro-fatty residuum) or excess anetodermic skin requiring excision. Moreover, regressed lesions can leave an unsightly bed of large, dysplastic veins, which respond well to sclerotherapy.

Some lesions may be difficult to differentiate from other tumours, such as congenital fibrosarcoma or rhabdomyosarcoma, and as such may warrant early biopsy and/or surgical excision. NICH may necessitate excision for aesthetic concerns as these lesions never involute.

Kaposiform haemangioendotheliomas are locally aggressive solitary vascular tumours, which are usually present at or soon

Figure 16.3 Clinical image of an infant with a large violaceous oedematous lesion typical of a kaposiform haemangioendothelioma.

after birth. This tumour often presents as a large violaceous oedematous lesion (Figure 16.3). Diagnosis can be confirmed with MRI, which shows a characteristic stranded, T2 hyperintensity, poorly defined margins and invasion of adjacent tissues. By 2 years of age, these tumours have usually undergone partial involution but complete involution does not occur. Kaposiform haemangioendothelioma is associated with *Kasabach–Merritt phenomenon*, characterized by thrombocytopenia $<25 \times 10^9/L$, petechiae and bleeding. The other tumour related to this phenomenon is *tufted angioma*, which has distinct clinical and histological features that distinguish it from kaposiform haemangioendothelioma. The primary treatment for kaposiform haemangioendothelioma is vincristine.¹⁶ Other therapeutic options include rapamycin and sirolimus.¹⁷ Platelet transfusion is contraindicated unless there is active bleeding or surgical intervention is planned. Although the primary indication for therapeutic treatment is Kasabach–Merritt phenomenon, drug therapy is also considered for large asymptomatic tumours to minimize fibrosis and consequent pain and stiffness.

Pyogenic granuloma is a small, solitary pedunculated red papule that commonly occurs in childhood. The primary complications associated with this lesion are bleeding and ulceration. These tumours have been treated with laser, curettage, electrocautery and shave excision, with a recurrence rate in excess of 40%. The latter is in view of the fact that these lesions extend into the reticular dermis and therefore effective management requires full-thickness resection.

Vascular malformations

Vascular malformations arise from abnormal development of vascular elements during embryogenesis. Although present at birth, vascular malformations typically only become evident in

childhood or occasionally, in adult life, do not undergo involution and grow commensurate with the child. Malformations are grouped into fast flow versus slow flow, with the former containing an arterial component. Genetic aberrations may give rise to vascular malformations, but the majority are non-syndromic and non-familial. Arteriovenous malformations may be caused by mutations in endoglin (hereditary haemorrhagic telangiectasia type 1, *HHT1*), activin receptor-like kinase 1 (*HHT* type 2), *RASA1* (capillary malformation–arteriovenous malformation) or *PTEN* (PTEN-associated vascular anomaly). Venous malformations can result from mutations in the *TIE2* (sporadic venous malformations, cutaneomucosal venous malformation), glomulin (glomovenous malformation), *CCM1/KRIT1*, *CCM2* or *CCM3* (cerebral cavernous malformations) genes. Mutations in *VEGFR3*, *FOXC2*, *SOX18* or *CCBE1* genes are responsible for primary lymphoedema.² Unlike infantile haemangiomas, vascular malformations tend to demonstrate an equal sex distribution.

Capillary malformations commonly present at birth as red cutaneous discolorations. Over time, the colour often deepens and the skin thickens to eventually adopt a raised ‘cobblestone’ appearance. A proportion of lesions are associated with contiguous soft tissue and bony hypertrophy. Traditionally, facial capillary malformations have been described as occurring in one of the three trigeminal nerve branch distributions (45%), with a greater proportion (55%) involving more than one dermatome or occurring bilaterally. However, there does not appear to be any pathophysiologic relationship with the trigeminal nerve. With capillary malformations in the so-called first trigeminal nerve distribution, *Sturge–Weber syndrome* should be considered.¹⁸ *Sturge–Weber syndrome* is a sporadic disorder, with an incidence of 1 in 50 000. The capillary malformation involves the first trigeminal nerve distribution, but may extend into the second and third (Figure 16.4). The two other cardinal features of this syndrome are ocular anomalies (choroidal vascular abnormalities, glaucoma) and leptomeningeal involvement (capillary, venous or arteriovenous malformations). Ophthalmology consultation and intracranial MRI examination are mandatory in these patients.

Midline capillary malformations are occasionally associated with CNS anomalies, such as encephalocele, occult spinal dysraphism, tethered spinal cord or arteriovenous malformations of the spinal cord (Cobb syndrome). Capillary malformations, particularly facial malformations, can result in significant psychological morbidity secondary to the disfigurement often associated with these lesions. Pulsed dye laser is now routinely offered as early as 1 year of age as a therapeutic modality. Laser treatment is highly beneficial in attenuating pigmentation and lessening the likelihood of developing secondary complications including darkening, dermal thickening and pyogenic granulomas. In later childhood, adolescence and into adulthood, surgical debulking may be required to correct any anatomic deformity.

Lymphatic malformations, often referred to as ‘cystic hygromas’ or ‘lymphangiomas’, result from aberrant development of lymphatic channels and are grouped into macrocystic, microcystic

Figure 16.4 Capillary malformation involving the first, second and third trigeminal nerve distributions bilaterally in a patient with *Sturge–Weber syndrome*.

or combined lesions, depending on the size of the malformed channels, with microcystic usually defined as containing cysts less than 1–2 cm in diameter.¹⁹ Macrocystic lesions are the most common subtype of lymphatic malformation and typically arise in the neck, although they occur in any anatomic region including mesentery, orbits and bladder. Lymphatic malformations can be apparent at birth, presenting as a large, soft, fluctuant swelling with absence of overlying skin discoloration (Figure 16.5). These lesions transilluminate and are usually non-tender. Some present later in life following an acute intralesional bleed, with firm, tender clot-filled cysts (Figure 16.6). Lymphatic malformations are also prone to sudden expansion with concurrent, usually viral, illness. Most lesions are easily diagnosed on ultrasound alone; however, MRI may be required to further define deep extension in complex lesions (Figure 16.7).

Microcystic lesions are firmer on palpation relative to their macrocystic counterparts. Moreover, the malformation may involve the contiguous skin and/or mucosa, presenting as vesicles, which may seep serous fluid or bleed. Microcystic

lesions often have a large connective tissue component and on MRI demonstrate localized tissue overgrowth with a high T2 signal and a diffuse mild enhancement pattern. Lymphatic malformations are occasionally combined with cutaneous capillary malformations and with venous anomalies, most commonly as a *Klippel-Trénaunay* type association in a lower limb. Differentiation between lymphatic and venous malformations can be facilitated with focused physical examination. Although both types of malformations are soft and compressible, unlike venous malformations, lymphatic lesions do not expand with Valsalva manoeuvre and the overlying skin is often normal or displays only a subtle bluish hue. Moreover, venous malformations are more diffuse and ill defined when compared with lymphatic lesions. Lymphatic malformations may cause significant morbidity secondary to mass effect, chylous effusions, recurrent infection (sepsis), bleeding, pain and deformity.

The first-line therapy for macrocystic or combined (macro-/microcystic) lymphatic malformations is usually percutaneous sclerotherapy, which involves the injection of a sclerosing agent into the cysts to collapse their walls and prevent their re-expansion (Figure 16.8). Sclerotherapy is also utilized to control recurrent

infection and intralesional bleeding. Over the last three decades, multiple sclerosant agents including OK-432, sodium tetradecyl sulfate (STS), ethanol, bleomycin and doxycycline have been used in the treatment of lymphatic malformations. In general, doxycycline, STS and bleomycin are currently the preferred sclerosants. Although microcystic lymphatic malformations tend to be less amenable to sclerotherapy, largely in view of the more solid nature of these lesions, some series have shown a good response rate with bleomycin.

The most common complications associated with sclerotherapy are infection, cutaneous ulceration and nerve injury; with these potential risks varying according to the agent used. Lymphatic malformations that fail to respond to sclerotherapy, can be considered for surgical resection. Seroma formation is the most common complication following surgical extirpation, and can be minimized by careful application of compressive dressings. Complex and extensive lesions are associated with more significant morbidity, including infection, delayed healing, peripheral nerve injury and deformity. Resection carries an important rate of recurrence, especially for lesions that involve multiple tissue planes where excision is usually incomplete (Figure 16.9).

Venous malformations may present earlier than lymphatic malformations due to the associated discoloration of the overlying skin. However, many are deep-seated and are not problematic until they grow with puberty.²⁰ Venous malformations exhibit variable morphology, from focal round lesions (often mistaken for haemangiomas) to diffuse and ill-defined lesions involving multiple tissue planes, or clusters of dysplastic veins involving the entire limb. Most commonly, venous malformations are restricted to subcutaneous tissue and muscle (Figure 16.10), though lesions may extend to deeper structures, with bone and joint involvement seen on imaging. In fact, venous malformations frequently occur around joints, particularly the knee, and as such cause symptoms with movement. Lesions can be associated with pain, swelling, bleeding and deformity (Figure 16.11). Moreover, extensive venous malformations can be

Figure 16.7 (a) Ultrasound image of the lymphatic malformation of the chest wall in the child shown in Figure 16.5. Cysts of varying sizes can be seen, separated by thin septae. (b) T2-weighted axial MRI image of the same lymphatic malformation. The majority of the macrocysts lie deep to the microcysts.

Figure 16.8 Clinical images of a macrocystic lymphatic malformation of the neck (a) before and (b) after a single sclerotherapy treatment.

associated with localized intravascular coagulopathy and phlebothrombosis. On physical examination, these lesions are found to enlarge with dependent positioning and Valsalva manoeuvre. Calcified phleboliths can often be palpated within the mass, and are pathognomonic on imaging, appearing as rounded signal voids. Ultrasound is useful to identify the slow flow nature of the lesion. On MRI, these malformations are hyperintense on T2-weighted imaging and, contrary to lymphatic malformations, enhance with contrast (often with a patchy distribution of enhancement due to the slow flow of contrast through the malformation) (Figure 16.12). Most malformations cause pain secondary to venous congestion and thrombus formation.

For venous malformations of the extremity, use of compression garments are recommended to reduce venous stasis, expansion, and localized intravascular coagulopathy. Like lymphatic malformations, sclerotherapy is usually the therapy of choice for treatment of venous malformations, with resection reserved for well-localized lesions that can be removed completely or malformations that remain symptomatic or cause important residual deformity despite sclerotherapy. The therapeutic mechanism of sclerotherapy for venous malformations is the same as for lymphatic malformations,

wherein the sclerosant induces fibrosis within the malformation, thereby reducing venous stasis and mass effect. For these lesions, STS and ethanol are the preferred sclerosants.

The complication rates are higher for venous sclerotherapy than for lymphatic lesions, given the more aggressive nature of the agents used for treatment of venous malformations. Both STS and ethanol are associated with a potential for tissue necrosis. When surgical resection is considered, caution must be exercised to avoid aggravating the existing deformity, and thus conservative resection is recommended especially in view of the fact that complete removal is often unattainable and recurrence is high. Some centres advocate the use of prophylactic aspirin for recurrent pain secondary to phlebothrombosis and low-molecular-weight heparin in patients with significant localized intravascular coagulation.

Two syndromes commonly associated with venous malformations are *Maffucci syndrome* and *blue rubber bleb naevus syndrome*. The former is characterized by cutaneous venous malformations, with enchondromas and/or bony exostoses. The latter includes multiple, small (<2 cm) venous malformations localized to skin, subcutaneous tissue and

Figure 16.9 The lymphatic malformation of the child in Figure 16.5 was initially treated with sclerotherapy, following which surgical extirpation was undertaken in view of the extent of the lesion and associated disability it engendered. Intraoperative photographs, including (a) markings of the malformation, (b) the malformation *in situ*, (c) chest wall and axilla following excision of the lesion, and (d, e) the excised malformation.

Figure 16.11 Clinical image of a venous malformation of the hand. The significant anatomic deformity caused considerable functional impairment.

most particularly the gastrointestinal tract. The recently proposed treatment of blue rubber bleb naevus syndrome is rapamycin (sirolimus).²¹

Klippel-Trénaunay syndrome is a capillary-lymphatic-venous malformation of an extremity (lower extremity in 95% of cases) with considerable soft tissue and bony overgrowth, often to disfiguring proportions (Figure 16.13). The malformation may extend to involve the pelvis. A large embryonic vein in the subcutaneous tissue of the lateral aspect of the leg and thigh (*marginal vein of Servelle*) is present. Management includes measures outlined to address the capillary, lymphatic and venous components of the malformation and requires a multidisciplinary approach.

Arteriovenous malformations are the rarest form of vascular malformation, although clinically they usually attract the most attention.²² These lesions arise from an error in vascular development during embryogenesis, where abnormal connections are created between arterial and venous systems without intervening capillaries. The latter developmental aberration results in vascular shunting, tissue overgrowth and arterial steal. Although some arteriovenous malformations remain small and inconsequential throughout life, others can demonstrate insidious growth, causing significant morbidity secondary to pain, ulceration, bleeding, tissue destruction and cardiac failure. The majority are located within the musculoskeletal tissues of the trunk and extremities. Lesions localized to the head and neck often have complex deep connections (Figure 16.14).

Figure 16.12 (a) T2-weighted axial MRI image of a venous malformation of the left cheek in a child. The malformation is visualized as a lobulated, well-defined mass within the subcutaneous tissue. (b) Intraoperative fluoroscopic image of sclerotherapy of the lesion. A two-needle technique was used to instill opacified sclerosant into the malformation. (c) T2-weighted axial MRI image of the same venous malformation following four sclerotherapy treatments. The malformation was considerably reduced in size and the distortion of the adjacent soft tissues of the cheek was lessened.

Figure 16.13 Clinical images of a child with a capillary-lymphatic-venous malformation of the lower extremity, demonstrating considerable overgrowth and distortion of the limb, characteristic of Klippel-Trénaunay syndrome.

Figure 16.14 Clinical image of an arteriovenous malformation of the ear.

Most malformations can be diagnosed on clinical examination, as a localized thrill and/or bruit is present and the soft tissues are typically warm and diaphoretic. Ultrasound can be used to confirm the diagnosis in difficult cases but there is generally no role for cross-sectional imaging. Angiography should be reserved for those cases where an interventional radiologist is planning to treat the lesion definitively. Schobinger proposed a classification system for arteriovenous malformations based on clinical characteristics. In stage I (quiescence), where the lesion is warm, pink and shunting is seen on colour Doppler examination. In stage II (expansion), there is enlargement of the

lesion, and a thrill or bruit may be noted. Stage III (destruction) is characterized by dystrophic skin changes, ulceration, bleeding and pain. Finally, in stage IV (decompensation) congestive heart failure is present.

Arteriovenous malformations remain the most challenging lesions to treat effectively. Management is complicated by the fact that these anomalies progress over time, complete extirpation is rarely possible, recurrence after treatment is high, and resection may be associated with significant morbidity and may result in more considerable deformity than the malformation per se. Liu *et al.*²³ recommend resection for Schobinger stage I and II arteriovenous malformations in non-anatomically sensitive areas, where progression to a higher stage will render extirpation more difficult or if there is an aggravation of symptoms or deformity, for stages I and II lesions respectively. Intervention for stage III and IV lesions is dictated by the degree of associated symptoms. Embolization should be considered as a first-line treatment for most lesions, as it is minimally invasive and can be directed to the point of shunting, traditionally called the *nidus* (Figure 16.15). The latter can also be implemented prior to surgical extirpation to reduce the size of the malformation preoperatively and intraoperative blood loss. Incomplete embolization or excision often stimulates the malformation to enlarge and become problematic. Thus, management of these complex lesions should remain the remit of an experienced multidisciplinary team.

Parkes-Weber syndrome is characterized by small, diffuse multifocal arteriovenous malformations with associated extremity overgrowth and an overlying pale capillary malformation. The *capillary malformation-arteriovenous malformation* is an autosomal dominant condition associated with *RASA1* gene mutation. Patients characteristically present with atypical capillary malformations that are small, multifocal pink lesions surrounded by a pale halo, and can be associated with internal arteriovenous malformations.

Figure 16.15 (a) Angiography image demonstrating a focal high flow arteriovenous malformation of the left ankle, which is supplied by the posterior tibial artery. (b) Angiographic image following embolization, demonstrating dense onyx material filling nearly the entire malformation while preserving the posterior tibial artery.

Conclusion

Management of vascular anomalies necessitates interdisciplinary care by a dedicated team with expertise in plastic surgery, dermatology, interventional/diagnostic radiology, general paediatric surgery, orthopaedic surgery, haematology/oncology, pathology and vascular surgery. Moreover, allied health professionals such as psychologists, occupational therapists and physiotherapists are also integral members of the team. In the majority of cases, the correct diagnosis can be made by thorough history and physical examination. Appropriate imaging and biopsy for histological analysis can assist where diagnostic ambiguity remains. Treatment depends on the nature, size and location of the lesion, associated symptoms and anatomic deformity. Ultimately, management demands a holistic approach, which renders this field of medicine such a challenging and rewarding speciality.

CHAPTER 17

Cleft lip

Marc C. Swan and David M. Fisher

Department of Paediatric Plastic Surgery, The Hospital for Sick Children, Toronto, Ontario, Canada

Embryology

Between the fourth and seventh weeks of gestation, the two medial nasal prominences of the frontonasal process fuse to form the intermaxillary segment (Figure 17.1), consisting of the premaxilla and prolabium. In addition, the two maxillary prominences merge, from which the lateral lip and maxillary arch elements arise. By week 7 of gestation, mesenchymal confluence follows apoptosis of the epithelial seams between the medial nasal and maxillary prominences, resulting in the formation of a complete upper lip. Failure of fusion of the medial nasal prominence with the ipsilateral maxillary prominence results in a unilateral cleft lip and, if replicated bilaterally, a bilateral cleft lip results. The ratio of unilateral left, unilateral right and bilateral cleft lip deformity is 6:3:1, respectively. The lateral nasal prominences form the alae of the nose and do not contribute to the upper lip. At the molecular level, several major signalling pathways, including *BMP*, *FGF*, *Shh* and *Wnt*, are critical for midfacial morphogenesis, and subtle abnormalities in any one of these processes may lead to oro-facial clefting.

Cleft lip is defined as a congenital abnormality of the primary palate. It may be complete, forme fruste or incomplete, unilateral or bilateral, and may be associated with a palatal cleft. The *forme fruste* cleft is qualified by a notch in the vermilion, from which a visible band or furrow may extend to the mid-nostril floor, and is associated with irregularity of the cleft-side alae. A *Simonart* band occurs in approximately 30% of patients with a unilateral cleft lip and palate, and describes the small soft tissue bridge, most often devoid of orbicularis oris muscle, that spans the lateral and medial elements of a cleft lip.^{1,2} The integrity of the underlying alveolus is probably of greater clinical relevance than the magnitude of the soft tissue band.

In the context of sporadic clefting, the risk of unaffected parents with one child with cleft lip $\pm$ palate having a second affected child is approximately 4%, whereas with two affected children, the risk increases to 9%.^{3,4} If one parent has a cleft lip $\pm$ palate, the risk of having an affected child is similarly around 4%, which increases to 17% for a second affected child.

The anatomical severity of the cleft has a direct influence on the recurrence risk in first-degree relatives, with the type of cleft being predictive of the type of recurrence.⁴

First reported in 1969, most obstetric units in the developed world now routinely offer a mid-trimester fetal anomaly ultrasound scan, with facial examination being advocated since 1984.^{5,6} Using two-dimensional antenatal ultrasound, a Norwegian study detected up to 57% of cases of cleft lip $\pm$ palate, of which 43% had an associated anomaly; no cases of isolated cleft palate were diagnosed antenatally.⁷ Diagnostic accuracy has improved with the advent of three-dimensional sonography, which has led to a sensitivity of 95% and a specificity of 92.3%.⁸ In high-risk populations (i.e. those with a positive family history of oro-facial clefting), detection rates of 100% have been achieved.⁹ Antenatal MRI offers no particular advantage over ultrasound for the diagnosis of cleft lip, but has significant potential in improving the diagnosis of isolated cleft palate.¹⁰

Clinical anatomy

The orbicularis oris is the highly complex sphincteric muscle of the lip which facilitates feeding, speech and oral continence.¹¹ It consists of four substantially independent quadrants – upper, lower, left and right – each of which contains a smaller pars marginalis and a larger pars peripheralis. The surface marking of the junction between the marginalis and peripheralis fibres is the border between the vermilion and skin. The pars peripheralis fibres fan out obliquely from the modiolus to interdigitate with the other muscles of facial expression (including zygomaticus major superiorly and depressor anguli oris inferiorly) and terminate within the dermis. Their role is primarily one of articulation and facial expression.

The midline philtral dimple of the non-cleft upper lip is flanked by symmetrical philtral columns that arise from each peak of the Cupid's bow and curve gently cephalad to the base of the columella. The ridges of the philtral column are created by dermal insertions of the pars peripheralis fibres as they interdigitate in the

Figure 17.1 Embryology of the primary palate. Failure of fusion of the medial nasal prominence and the ipsilateral maxillary prominence results in a unilateral cleft lip.

midline, each crossing approximately 5 mm into the contralateral half of the upper lip. The Cupid's bow peaks are created by the pull of the levator labii superioris fibres inserting into the base of the ipsilateral philtral column.¹² The cutaneous roll (alternatively, the 'white roll' of Gillies or the 'white skin roll' of Millard) is the mucocutaneous junction between the vermillion and skin. The cutaneous roll runs from commissure to commissure, but is most prominent centrally at the Cupid's bow and gradually attenuates laterally. It contains four to five rows of progressively superficially positioned pilosebaceous units containing tiny unpigmented silky vellus hairs, which, by reflecting ambient light, highlight the contour of the Cupid's bow. The vermillion has an associated midline tubercle caused by the eversion of opposing pars marginalis fibres. The vermillion-mucosal junction ('red line' of Noordhoff) represents an abrupt transition between the keratinized vermillion and thick non-keratinized squamous epithelium of the oral mucosa.¹³

In the unilateral cleft lip, the Cupid's bow is preserved in the medial lip element. The lip height, as measured from the cleft-side peak of Cupid's bow to the base of the columella, is characteristically deficient and the bow is sloped. The cutaneous roll of the entire length of the bow is well preserved. However, there is vermillion height deficiency below the cleft-side half of Cupid's bow.¹³ The proposed peak of Cupid's bow on the lateral lip element has traditionally been less well defined. Noordhoff advocated preserving the proposed base of the philtral column as it is an anatomically determined landmark. He defined it as being located at the point where the cutaneous roll and the vermillion-mucosal junction begin to converge medially (Figure 17.2).¹⁴ At 'Noordhoff's point' there is adequate vermillion height (usually matching the height of the vermillion below the non-cleft side peak of Cupid's bow) and good-quality

Figure 17.2 Infant with a complete left cleft lip and palate. The cardinal position of Noordhoff's point is marked.

cutaneous roll. Medial to Noordhoff's point, the quality of these features diminishes.

The height of the lateral lip element (as measured from the subalare to Noordhoff's point) is frequently different from the height of the non-cleft side (subalare to Cupid's bow peak). The latter is often excessive in incomplete clefts and usually shorter in complete clefts.^{15,16} The transverse length of the lateral lip element (Noordhoff's point to the commissure) is almost always shorter than that of the non-cleft side (Cupid's bow peak to the commissure). Lateral lip element hypoplasia, defined as combined height and transverse length deficiency, is present in almost two thirds of patients with a unilateral cleft.¹⁶

The orbicularis oris muscle is misdirected by the cleft (Figure 17.3).^{17,18} On the cleft side, the pars superficialis changes direction as it approaches the cleft to run almost vertically to find insertion to the cleft-side nostril and periosteum of the piriform aperture. The pars peripheralis inserts into the lateral aspect of the alar and the nasolabial fold; contraction of the lateral lip element orbicularis produces a noticeable bulge in the lateral lip. On the non-cleft side, the orbicularis fibres insert into the base of the columella and nasal septum. Activation of orbicularis exacerbates the nasal deformity by splaying the alar cartilages, broadening the nasal tip, shortening the columella, and deviating the nasal septum to the non-cleft side. Successful correction of the unilateral lip deformity must address these aberrant muscular attachments.

In complete bilateral cleft lip and cleft palate, the prolabium and premaxilla are entirely separated from the lateral lip and maxillary arch elements. The dimensions of the prolabium will vary considerably between affected individuals, but there are some consistent findings. The cutaneous portion of the philtrum is devoid of the dimple and ridges that, in the non-cleft lip, define the shape and dimensions of the philtrum. The cutaneous roll of the prolabium is typically poorly defined when compared with the lateral lip elements, although it is usually

better preserved in an incomplete bilateral cleft lip. The height of the prolabial vermillion is inadequate with the superior labial sulcus being shallow or, in some patients, entirely absent. Orbicularis muscle does not enter the prolabium, and therefore lies passively upon the premaxilla, which is protruded and may, in extreme cases, adopt a horizontal posture. The lateral lip elements in the bilateral cleft are similar to the lateral lip element of a unilateral cleft.

The inferior and superior labial arteries (which arise from the facial artery at the modiolus) are the primary blood supply to the lips (Figure 17.4).¹⁹ They course close to the free border of the upper and lower lips, lying deep to the orbicularis muscle, juxtaposed to the mucosa, to anastomose with its fellow from the opposite side. The facial artery continues cranially along the

line of the nasolabial fold, and after giving off the lateral nasal branch, becomes the angular artery, which then anastomoses with the dorsal nasal artery. The ascending septal branches of the superior labial artery nourish the columella and anastomose with the terminal branches of the anterior ethmoid artery and the lateral nasal artery.

In the unilateral cleft, the superior labial artery on the cleft side is unable to pass horizontally through the lip and therefore anastomoses with the ipsilateral lateral nasal artery. The resultant interruption of the upper lip arterial arcade is of little surgical importance in unilateral cases due to the density of collateral blood supply. However, in complete bilateral clefts, the prolabium receives no input from either the superior labial arteries or, indirectly, via the greater palatine arteries, and is therefore entirely

reliant upon the terminal branches of the posterior septal artery (arising from the sphenopalatine artery), the anterior ethmoid artery and the lateral nasal artery.

The characteristics of the nasal deformity in the complete unilateral cleft were first described in 1931, and consists of a depressed cleft-side nasal dome and splayed alar cartilages, with eversion of the alar rim and exposure of the nasal lining.²⁰ The cleft medial and lateral crura are not believed to be hypoplastic based on both cadaveric dissections and intraoperative observations.^{21–23} The cleft alar base is depressed due to the underlying maxillary hypoplasia. Further, anomalous insertion of orbicularis oris into the alar base retracts it both laterally and inferiorly. The nasal spine, caudal nasal septum and columella, together with the premaxilla, are deviated to the non-cleft side due to the unopposed action of the aberrant insertion of orbicularis oris. Nasal obstruction may result from septal deviation, turbinate hypertrophy, or obstruction of the external nasal valve by nasal webbing. In the bilateral cleft nose, the columella is typically short or nearly absent due to deficient soft tissue and the septum may be excessively broad.

Preoperative assessment

It is essential to ensure that the infant is optimized prior to surgery; significant comorbidities are common in syndromic children and will inevitably require specialist paediatric input. Early liaison with the cleft anaesthesia team is recommended, particularly if there are potential airway concerns. Failure to thrive is seen in approximately 40% of children with a palatal cleft and 9% of those with an isolated cleft lip, thus all cleft patients must be closely monitored preoperatively to ensure that they are gaining weight appropriately.²⁴ Close cooperation between the family and the cleft unit (via the clinical nurse specialist, dietician and feeding specialist) is essential at this stage.

Although probably less controversial than the timing of palatal closure, currently no global consensus exists for the optimal timing for cheiloplasty. In 1966, Wilhelmsen and Musgrave proposed the 'rule of tens' as a criterion for lip surgery. Namely, weight greater than 10 pounds (4.5 kg), haemoglobin over 10 g/dL and age over 10 weeks (which replaced a white cell count of less than 10×10^3 per mm³ in their original iteration).²⁵ Millard observed that lip closure could occur at any time from birth to old age, and he advocated waiting until the child was three months of age as this achieved the best results in his opinion.²⁶ Indeed, the majority of cleft centres defer surgery until the age of 3–6 months, since it allows the optimization of underlying medical issues, minimizes the anaesthetic risks, and allows time for presurgical orthopaedic treatment if indicated.

Straith performed neonatal lip repair under local anaesthesia in the 1940s²⁷ and many cleft centres continue to perform neonatal cleft lip repair, sometimes as early as 48 h of age.²⁸ It has been argued that with modern specialist neonatal care and anaesthetic support, the perioperative risks are minimized, and

neonatal repair potentially facilitates improved integration of the child into the family network. There is little evidence to suggest that operating on neonatal cleft lips is unsafe.^{29–31} Although parents may express preference for earlier surgical intervention, there is no evidence of significant psychological morbidity in mothers when delaying repair until the age of three months.^{32,33}

The concept of an intrauterine cleft lip repair has garnered much interest due to the potential for scarless wound healing prior to 24 weeks gestation.³⁴ Furthermore, fetal repair might reasonably be expected to reduce the magnitude of the secondary 'downstream' dentoalveolar and midfacial deformities.³⁵ However the technical challenges are vast, and although feasible in both small (murine and lapine) and large (ovine) animal models, albeit with guarded aesthetic and functional results, the perceived benefits of fetal repair do not currently outweigh the significant risks of such early intervention.^{36–39}

The role of preoperative microbiological analysis in an attempt to predict the nasal and oropharyngeal flora at the time of cleft surgery is unhelpful, and culture results appear to have no influence on postoperative outcome, regardless of whether antibiotics were used.⁴⁰ If children with an unrepaired cleft lip and palate undergo preoperative microbiological analysis (with swabs taken from the nasopharynx and oropharynx), approximately 30% will have positive cultures, with the predominant pathogen being *Staphylococcus aureus*; beta-haemolytic streptococci were isolated in a small proportion of patients.⁴¹ The clinical significance of these results is unclear and debate continues as to whether preoperative microbiology analysis is justified. The evidence for cancelling an elective cleft procedure if a child has a concurrent upper respiratory tract infection remains ambiguous, although most cleft surgeons are cognizant of the increased postoperative risks, and would therefore be reluctant to proceed, favouring an honourable deferral for four weeks until the child has fully recovered.⁴²

A typical treatment pathway, from antenatal diagnosis to adulthood, for a child with a unilateral complete cleft lip and palate, as practised at The Hospital for Sick Children in Toronto, Canada, is outlined in Table 17.1. Although a child with an isolated incomplete cleft lip may require just the single operation, the burden of care in the case of a complete bilateral cleft of the lip and palate is far more substantial.

Presurgical orthopaedics

Historically, the first record of facial binding in order to realign the premaxilla in a complete bilateral cleft was in 1686.²⁶ In the context of a complete unilateral cleft lip, presurgical orthopaedics (PSO) is defined as the use of a device to improve the alignment of the maxillary arch segments in order to facilitate lip repair, and was first reported by McNeil in 1950 by utilizing a removable intraoral plate, and subsequently popularized by Burston.^{43,44} The principles have also been applied to the complete bilateral cleft lip in order to correct the protruded premaxilla.

Table 17.1 Typical surgical treatment pathway for a child with a unilateral complete cleft lip and palate

Age	Treatment
Prenatal diagnosis	Genetic counselling (if requested by family) Parental consultation with cleft surgeon
2 weeks	Presurgical orthopaedics (if indicated)
3–6 months	Cleft lip repair and primary nasal correction
10–14 months	Palate repair ± grommets
≥3 years as required	Lip revision (if indicated)
≥4 years as required	Surgical correction of velopharyngeal incompetence (if indicated)
≥7 years as required	Lobule rhinoplasty (if indicated)
8–10 years (mixed dentition)	Alveolar bone graft
≥7 years as required	Definitive septorhinoplasty (if indicated)
≥16–18 years (skeletal maturity) as required	Orthognathic surgery (if indicated)

**Figure 17.5** Nasoalveolar moulding plate *in situ* with left nasal stent evident in a three-month old infant with a complete unilateral cleft lip and palate.

PSO devices may be passive, such as a dental plate or facial strapping, or active, such as Latham's appliance, which is pinned to the child's maxilla, and is adjusted by turning an integral coaxial screw, that gradually aligns the alveolar segments.⁴⁵ In 1999, Grayson *et al.* introduced the concept of nasoalveolar moulding (NAM), whereby the oral plate has nasal prong extensions that are able to reposition the deformed nasal cartilages and lengthen the columella (Figure 17.5).⁴⁶ The resultant approximation of the alveolar segments allows the surgeon to perform a primary gingivoperiosteoplasty at the time of the lip repair, which is said to limit the need for secondary alveolar bone grafting in up to 60% of patients.^{47,48} In those institutions who do not practise PSO/NAM, alternative strategies can be utilized to reduce alveolar cleft width, such as single-layer vomerine flap closure of the hard palate at the time of lip repair, with subsequent secondary bone grafting of the alveolus.^{49–51}

In spite of considerable enthusiasm for the deployment of PSO/NAM by its proponents, its adoption is by no means universal, with some units reserving its use for more severe deformities such as the wide unilateral cleft or asymmetrical bilateral cleft, while many units do not offer it as a treatment option. This may, in part, reflect concerns regarding the additional burden of care placed on families undergoing PSO/NAM treatment with the associated healthcare costs incurred. Moreover, robust evidence in support of the long-term positive effects of PSO or NAM is lacking, although, as any surgeon who has struggled with a difficult primary lip repair may testify, the short-term benefits cannot be completely ignored. A recent systematic review of the literature failed to demonstrate a long-term benefit to the use of PSO,⁵² and a systematic review examining the evidence for NAM reported that although there is a trend towards a positive effect, the results are inconsistent regarding long-term changes in nasal symmetry.⁵³ In 2013 Sommerlad presented the interim results of a randomized controlled study comparing PSO with controls in complete unilateral cleft lip and palate patients; no difference in aesthetic or functional outcomes could be discerned at their 5-year and 10-year audit assessments.^{54,55} The issue of PSO/NAM has a tendency to polarize opinion in the worldwide cleft community; a position that is unlikely to change until randomized controlled trial evidence with long-term follow-up becomes available for scrutiny.

Unilateral cleft lip repair

The first recorded cheiloplasty was performed in China in AD 390.⁵⁶ In renaissance Europe, Paré was extremely influential, with contemporaneous texts describing the scarification ('paring') of the cleft margins and approximation of the raw edges using needles and sutures.⁵⁷ Husson first recognized that by creating curved incisions, a degree of lengthening of the lip repair could be achieved on wound apposition; a technique later refined by both Rose and Thompson.^{58,59} In 1844 Mirault identified that straight-line scars resulted in unsightly lip shortening, with the potential for notching, and introduced the concept of a triangular flap from the lateral lip element to both lengthen the lip and disrupt the scar.⁶⁰ In 1949, LeMesurier recognized the importance of reconstructing the Cupid's bow using a quadrilateral flap from the lateral lip element, although it was Tennison who preserved the anatomy of the bow, and Randall who reduced the size of the triangular flap.^{61–63} Millard introduced his rotation-advancement technique in 1957, which has subsequently undergone numerous modifications.^{64,65} In 2005 Fisher published his anatomical subunit approximation technique, which utilizes the wound-lengthening principles of Rose and Thompson with the anatomic subunit approach of Berget and Mennick.^{14,66,67}

Principles of surgical repair

Regardless of the surgical technique employed, the principal goals of unilateral cleft lip repair remain constant. These include approximation of the medial and lateral lip elements at all levels

(i.e. nostril sill, cutaneous roll, vermillion–cutaneous junction and vermillion–mucosal junction) without loss of natural landmarks. Balance should be achieved by providing length where tissue is short and excision where height is excessive; poor-quality tissue at the cleft margins should ideally be discarded. The scar of union should be placed along natural lines, with appreciation of the anatomical subunits of the nasolabial complex. The nostril margins should be of equal circumference and the alar bases should be symmetric from the anterior view, with careful attention paid to reconstruction of a natural ‘nostril sill roll’.⁶⁸ Complete release of the aberrant attachments of the orbicularis oris muscle must be performed before undertaking a functional muscle reconstruction.

The height of the non-cleft side (i.e. the philtral column length from the lip–columellar crease to the Cupid’s bow peak) provides the dimension that must be created by the cleft-side reconstruction. The medial cleft-side height (i.e. the philtral column length from the lip–columellar crease to the projected Cupid’s bow peak) is short and will necessitate lengthening from the lateral cleft-side lip height. The entire length of the Cupid’s bow should be preserved in the medial lip element. In the lateral lip element, Noordhoff’s point should be conserved and used to form the base of the philtral column incision. The cutaneous roll of the medial and lateral lip elements should be approximated in a side-to-side fashion (creating a ‘butt joint’). Vermillion height deficiency below the cleft-side half of Cupid’s bow should be augmented, with attention paid to recreating a level vermillion–mucosal junction.

Operative techniques

Tennison–Randall inferior triangle repair

The inferior triangle repair is a Z-plasty where the middle limb of the Z is shared by the incised medial and lateral cleft margins (Figure 17.6). Whereas Tennison used a bent wire to stencil

equal limbs of the Z-plasty scar, Randall refined the technique using calipers and geometric planning in order to minimize the size of the inferior triangle.^{62,63} The total lip height of the non-cleft side is measured from a reference point in the nostril sill to the peak of the ipsilateral Cupid’s bow. The greater lip height is measured on the medial cleft side from the proposed medial point of closure at the height of the lip in the nostril sill (symmetric with the reference point in the non-cleft-side nostril sill) to the peak of the cleft-side Cupid’s bow. The difference between the total lip height and the greater lip height (i.e. the lesser lip height) stipulates the base width of the inferior triangle required to level Cupid’s bow.

There are a number of advantages of the inferior triangle repair. First, nostril sill closure is accomplished by simple side-to-side approximation of the medial and lateral nostril sill elements, with resultant scarring at the base of the nose being kept to a minimum. Second, adequate lengthening of the medial lip height can be achieved even when the medial lip height is very short. Furthermore, the position of Noordhoff’s point need not be compromised when the lateral lip height is short, due to the lengthening effect of the Z-plasty. The repair may be criticized due to the non-anatomical alignment of the Z-plasty scar and the fact that secondary revisions may be hampered by the presence of the sizeable triangular flap.

Millard rotation–advancement repair

The rotation–advancement technique is reported to account for the majority of lip repairs performed worldwide.⁶⁹ The ‘rotation flap’ is created by a curvilinear incision directed along the medial lip element, such that it mirrors the non-cleft-side philtral column in its lower half (Figure 17.7).⁶⁴ The incision then gently arcs into the territory of the philtrum and approaches (but should never cross) the non-cleft-side philtral column. This permits caudal rotation of the cleft-side peak of Cupid’s bow, and the resultant defect is resurfaced with a large triangular ‘advancement’ flap from the lateral lip element. The triangular portion of prolabial skin lateral to the ‘rotation flap’ forms the ‘columella base flap’, or ‘c-flap’, which rotates cranially to reconstruct the cleft-side nostril sill. Millard noted that the rotation of Cupid’s bow was often inadequate and subsequently introduced a ‘back-cut’,⁶⁵ which extends from the most cranial point of the rotation incision down the philtrum just medial to the non-cleft-side philtral column. The resultant defect is now quadrilateral-shaped (rather than triangular) and can be filled by caudal rotation of the ‘c-flap’, however this risks lowering the transverse limb of the repair.

The main appeal of this repair is the ‘cut-as-you-go’ approach and the preservation of the Cupid’s bow and philtral dimple. In the lower portion of the lip, the scar mirrors the non-cleft-side philtral column, however the aesthetic result is compromised in the upper half of the lip as the scar fails to emulate a normal philtral column. Furthermore, excessive scarring is created at the base of the nose, and if the ‘c-flap’ is utilized to backfill the secondary defect created by the back-cut, it can no longer

Figure 17.6 The inferior triangle repair of Tennison as modified by Randall. Source: Randall, 1959.⁶³ Reproduced with permission of Lippincott Williams & Wilkins.

contribute to closure of the nostril sill, with the resultant risk of potential nostril stenosis. The cleft-side alar base incision in Millard's original description produces a noticeable scar and is therefore best avoided; indeed many surgeons believe that such an aggressive alar base incision is unnecessary. The length of the marginal incision at the lateral lip must be of sufficient length to marry up with the full length of the corresponding rotation incision. In the case of a complete cleft with a vertically short lateral lip element, it may be necessary to extend the incision beyond Noordhoff's point in order to achieve adequate vertical height, which will further compromise the transverse length of the lateral lip. A criticism of the Millard technique, particularly in the wide cleft, is that it tends to produce a 'short' lip, which can be 'vertically short' if related to an inadequate rotation incision or back-cut, or 'transversely short' if Noordhoff's point is violated.⁷⁰

In 1987, Mohler published a modification to the standard rotation-advancement repair in an attempt to produce a scar that is more symmetric with the non-cleft philtral column in the upper half of the lip (Figure 17.8).⁷¹ The curve of the rotation incision is straightened such that it extends into the columella base rather than towards the non-cleft philtral column. A 90° back-cut is created to the level of the labio-columella crease, which allows the columella tissue to descend by transposing a Z-plasty into the lip such that the 'advancement flap' is not required to encroach as medially, thus improving the lie of the scar. A relative contraindication to this approach is therefore a narrow columella.¹⁴ The resultant transverse limb of the repair is elevated such as to lie inconspicuously within the lip-nose junction. In common with all rotation-advancement repairs, the Mohler modification is prone to compromise of the transverse lateral lip length when the lateral lip is vertically short.

Noordhoff also modified Millard's original repair.¹⁴ In the 'Chang Gung repair', if rotation of Cupid's bow is inadequate, a small opening back-cut is created just above the cutaneous roll at the cleft-side peak of Cupid's bow, into which is incorporated a small triangular flap from the lateral lip element. As well as providing additional height, the triangular flap also

Figure 17.8 Mohler's modification of the 'rotation-advancement' repair with extension of the rotation incision into the columella and a right-angled back-cut to allow transposition of a Z-plasty into the lip. Source: Mohler, 1987.⁷¹ Reproduced with permission of Lippincott Williams & Wilkins.

helps to accentuate the pout of the lip. Noordhoff also augmented the deficient vermilion below the cleft-side Cupid's bow by means of a laterally based vermilion flap. Numerous additional modifications have been made to Millard's original 'rotation-advancement' approach, with Stal *et al.* providing a comprehensive account of the evolution of the technique.⁷²

Fisher anatomical subunit approximation repair

The anatomical subunit approximation technique aims to produce a cutaneous scar along the 'ideal line of repair' (Figure 17.9).⁷³ The incision on the medial cleft side ascends from a point above the cutaneous roll such that it mirrors the ridge of the non-cleft philtral column. It then curves superolaterally along the lip–columellar crease to the medial point of closure in the nostril sill. Lip length is achieved by two mechanisms: the previously described Rose–Thompson principle (which accounts for approximately 1 mm of lengthening) and, if required, a small inferior triangle from the lateral lip element, which is positioned just superior to the cutaneous roll (a modification of the Tennison–Randall repair). The lengthening achieved by the Rose–Thompson principle significantly reduces the size of the inferior triangle that would otherwise be required had a traditional inferior triangle repair been performed. The technique also utilizes a Noordhoff's lateral vermilion triangle flap to augment the deficient vermilion height of the medial lip element on the cleft side.

This technique has a number of advantages over the inferior triangle and rotation–advancement repairs. In variance with the Millard technique, there is minimal scar at the base of the nose. The lip scar is positioned along the seams of anatomical subunits with the exception of, when required, a small triangle above the cutaneous roll. Tension is ideally positioned above the roll. Continuity of the cutaneous roll is achieved by side-to-side approximation of the roll elements. In common with the inferior triangle repair, lateral lip transverse length need not be compromised to achieve vertical height.

A summary of the skin markings for the anatomical subunit approximation technique is highlighted in Figure 17.9. The Cupid's bow and philtral column heights are marked in the standard fashion, with the cleft-side bow peak and philtral column heights being equidistant relative to the midline as the corresponding non-cleft-side markings. Note that the non-cleft-side Cupid's bow peak is not marked at the highest point of the curve of the lip, but rather where the straight portion of the

non-cleft-side half bow meets the convexity of the lateral lip element, as may be appreciated in Figure 17.9. No such convexity exists on the cleft side of the medial lip element. Therefore, the curve of the bow on the cleft side will come from the lateral lip element lateral to Noordhoff's point.

The point of origin of the opening incision for the medial lip back-cut is then located just above the cutaneous roll (the 'supra-white roll point') at a point in line with the cleft-side bow peak and perpendicular to the vermilion–cutaneous junction. Caudally, from this point, the incision line will continue across the free border of the lip into the mucosa. The medial lip incision (equivalent to the 'greater lip height') will ascend from the supra-white roll point to the height of the cleft side philtral column (within the lip–columellar crease). The incision line then traverses superolaterally to the medial point of closure in the nostril sill (equivalent to the 'third height').

The medial and lateral points of closure within the nostril sill are not distinct anatomical points and are arguably the hardest points to define in this repair. The medial point of closure in the nostril sill is positioned lateral to the curve of the lip–columellar crease. It will be positioned more medially in complete cases and more laterally in incomplete cases. The lateral point of closure in the nostril sill is then chosen on the lateral lip element, relative to the medial point of closure in the nostril sill, such that when these two points are approximated, two goals are accomplished: nares of equal circumference and symmetry of the alar bases from the anterior view. Gentle manipulation of the medial and lateral lip elements should confirm acceptable positioning of these points. In complete clefts where the lateral lip is tethered such that the medial and lateral lip elements cannot be brought together, it is advisable to release the lateral lip element first.

Calipers are used to measure the 'total lip height' and the 'greater lip height'. The 'total lip height' is measured with the lip at rest and is defined as the distance from the height of the non-cleft philtral column (at the lip–columellar crease) to the non-cleft-side supra-white roll point (i.e. the non-cleft side equivalent to the point of origin of the opening incision for the medial lip back-cut). The 'greater lip height' is measured with gentle downward traction on the lip to unfurl the medial lip and is defined as the distance from the height of the cleft-side philtral column (at the lip–columellar crease) to the point of origin of the opening incision for the medial lip back-cut. The 'lesser lip height' (equivalent to the base width of the small inferior triangle) is equal to the 'total lip height' minus the 'greater lip height' and less 1 mm (Figure 17.10). The 1 mm accounts for the approximate length achieved by the Rose–Thompson principle. If an inferior triangle is required, the back-cut for the opening incision is drawn perpendicular to the 'greater lip height' incision, and of a length equal to the 'lesser lip height' (the inferior triangle being equilateral). The back-cut rotates the cleft-side peak of Cupid's bow caudally. The 'lesser lip height' is usually between 1 and 1.5 mm and never exceeds 2 mm. For incomplete clefts, an inferior triangle is often not necessary.

Figure 17.9 The anatomical subunit approximation technique as described by Fisher. Key markings are shown, including the total lip height, greater lip height, lesser lip height and the third height.

Figure 17.10 The total lip height (*a*) and greater lip height (*b*) are measured from points just above the cutaneous roll (the supra-white roll point) at the bow peaks to the height of the ipsilateral philtral column in the lip–columellar crease. The base width of the inferior triangle (*c*) can then be calculated. Approximately 1 mm of lengthening occurs by the Rose–Thompson principle, thus reducing the size of the inferior triangle.

With respect to the lateral lip, Noordhoff's point is marked along the vermillion–cutaneous junction at the point where the cutaneous roll and red line begin to converge medially, as previously described (Figure 17.2). The natural convexity of the cutaneous roll lateral to Noordhoff's point is ideally suited for reconstruction of the cleft side curve of the bow. A supra-white roll point is marked above the cutaneous roll both in line with Noordhoff's point and perpendicular to the vermillion–cutaneous junction. Between the lateral point of closure in the nostril sill and the supra-white roll point on the lateral lip, three lengths must be accommodated: the greater lip height, the lesser lip height and the 'third height' (corresponding in length to the line connecting the height of the cleft-side philtral column and the medial point of closure in the nostril sill). This is readily achieved by placing the greater lip height caliper on the lateral lip element such that its lower tip lies the lesser lip height distance away from the supra-white roll point and its upper tip lies the third height distance away from lateral point of closure in the nostril sill.

In the scenario of a complete cleft with a short vertical height to the lateral lip element, the angle of the greater lip height incision will be more horizontal and, in extreme cases, may be confluent with the upper limb incision of the inferior triangle (Figure 17.11a). The contrary position is seen in an incomplete cleft with a relative excess of vertical height; the third height may be lengthened by lateralizing the medial and lateral points of closure within the nostril (Figure 17.11b). If vertical height excess persists in spite of this manoeuvre, it may be necessary to perform a medially based wedge excision of the upper lip below the lateral point of closure in the nostril sill (Figure 17.11c). The

Figure 17.11 Lateral lip markings vary depending on the vertical height of the lateral lip element. Note that the position of 'Noordhoff's point' is not compromised regardless of the lateral lip height.

lateral apex of this wedge excision should never extend laterally beyond subalare as this is unnecessary and leaves an unsightly scar. Care should be taken not to alter the vertical height of the lateral point of closure in the nostril sill as this will compromise the final vertical height of the alar insertion.

The vermillion deficiency below the cleft-side half of Cupid's bow requires augmentation. An opening incision is created along the vermillion–mucosal junction below the cleft-side half of Cupid's bow. This back-cut will receive a laterally based vermillion triangular flap from the lateral lip element as described by Noordhoff.

In incomplete clefts a wedge excision of the nostril sill above the medial and lateral points of nostril sill closure is performed. The excision should be sufficient to balance the circumference of the nares, with great care taken not to over-resect as the resultant nostril stenosis presents an unenviable reconstructive challenge. The mucosa of the cleft margins is removed by wedge excision; a short lateral upper buccal sulcus advancement incision may be helpful on occasions.

In complete clefts, the mucosal incisions on the medial and lateral lip elements extend cranially to the points of attachment of each lip element to the greater and lesser alveolar segments, respectively. An upper buccal sulcus incision extending laterally from the point of attachment of the lateral lip element is made. From the medial point of closure in the nostril sill, the incision continues intranasally along the caudal margin of the septum for a distance of up to 12 mm to facilitate access for septal repositioning. The lateral free edge of the septal flap will receive the medial free edge of the lateral vestibular flap. The lateral vestibular flap is fashioned by incising from the lateral point of closure in the nostril sill to the attachment point of the lateral lip element to the alveolus and then along the piriform margin to allow supra-periosteal mobilization of the alar base. An anteriorly based inferior turbinate flap may be required to augment nasal floor closure in clefts with a significant anteroposterior distance between the greater and lesser maxillary segments.

Bilateral cleft lip repair

A fundamental advantage in bilateral cleft lip deformity is that of symmetry, however the philosophical approach to managing the premaxilla has evolved significantly over time.²⁶ In 1556, Franco erroneously advocated primary excision of a protruding premaxilla – a practice now universally condemned. Fortunately others subsequently recognized its importance and attempted to preserve it, often using quite elaborate devices to provide compression or traction in an attempt to correct its alignment.⁷⁴ As the significance of the reconstructed orbicularis muscle in moulding the underlying premaxilla became recognized, the benefits of soft tissue closure over surgical setback on maxillary growth became evident.^{75,76} The concept of a staged reconstruction by utilizing a temporizing lip adhesion has gained widespread acceptance.² The destiny of the prolabium has provoked much debate, as techniques were devised to relocate it within the columella, the lip, or both. With a small prolabium, the importance of maintaining length of the frontonasal component was the motivation for using lateral lip skin flaps to augment below the prolalial component.⁷⁷ In 1965 Manchester described a single-stage closure in which the prolabium is left attached to the premaxilla, the mucosa unrolled and the lateral lip elements sutured to the sides of the prolalial component, without a muscle repair.⁷⁸ This technique therefore *preserved* the prolalial cutaneous roll and vermillion. Conversely, Millard's fundamental contribution was to *discard* the prolalial cutaneous roll and vermillion and introduce the lateral lip elements in order to achieve a single-stage bilateral lip closure. He also promulgated the concept of forked flaps to lengthen the columella.^{79,80} Talmant favoured an unscarred Cupid's bow and, in a variant of the Manchester technique, preserved a large triangular mucosal flap from the prolabium to provide enhanced volume to the central tubercle.⁸¹ Mulliken, in an adaptation of the Millard technique, also discards the prolalial cutaneous roll and vermillion.⁸² He utilizes presurgical orthopaedics by means of the Latham appliance and creates a narrow biconcave prolalial flap, establishes a median tubercle from the lateral labial elements, and aims to anatomically realign the alar cartilages.

The principles of bilateral cleft lip repair were outlined by Mulliken and include: the maintenance of symmetry (i.e. simultaneous bilateral lip repair), primary muscle reconstruction, adequate reduction of the prolabium, reconstruction of the median tubercle and Cupid's bow from the lateral lip elements, and primary rhinoplasty.⁸² PSO/NAM is commonly employed to control of the protruded premaxilla and to reduce the risk of the lateral alveolar segments collapsing medially thus creating a 'locked out' premaxilla.⁶⁸ A bilateral lip adhesion may be considered if PSO/NAM is either unavailable, not tolerated by the patient/family, or has been unsuccessful in correcting the premaxilla. The aim is to restore continuity to the upper lip such that it provides a physical constraint to the growth of the premaxilla. The incisions are designed so as to preserve the landmarks necessary for a subsequent definitive lip repair.² Premaxillary setback is no longer recommended as a primary procedure due to the deleterious effects on midfacial growth.⁸³

Mulliken initially advocated a two-staged repair, however he subsequently abandoned the use of forked prolalial flaps in favour of a single-stage repair (Figure 17.12).⁸⁴ He found that sufficient primary columellar lengthening and nasal tip projection could be achieved in a single procedure by manipulation of the alar cartilages (which are splayed and rotated caudally). He ceased creating an additional vertical nasal tip incision and accessed the alar cartilages via bilateral rim incisions alone. As the prolalial cutaneous roll and vermillion is of poor quality and should be discarded, Mulliken recommended a biconcave prolalial flap that is 2–2.5 mm wide at the lip–columellar angle and 3.5–4 mm wide between the bow peaks. The upper labial sulcus is invariably deficient in complete bilateral cleft lips and is usually augmented by a caudally based prolalial mucosal flap that is draped over the premaxillary periosteum in order to reconstruct the posterior wall of the upper labial sulcus.

Fisher's method of bilateral lip repair utilizes a tie-shaped prolalial shield flap, although this may be modified depending on the ethnicity of the patient and the parental appearance.⁸⁵ The dimensions of the prolalial flap in a 4- to 6-month-old child are typically 2.5–3 mm wide at the lip–columellar junction, 3.5–

Figure 17.12 Mulliken's method of single-stage bilateral complete cleft lip repair. Source: Kohout *et al.*, 1998.¹⁰³ Reproduced with permission of Lippincott Williams and Wilkins.

Figure 17.13 Fisher's surgical markings for repair of a complete bilateral cleft lip. Points on the patient's left side are described, with the corresponding right-sided points assigned the prime (') symbol. The corners of the prolabial skin are marked 3 and 4; 1 and 2 denote its height. Point 5 is just lateral to the lip–columellar crease. Point 6 denotes Noordhoff's point. Point 7 is the supra-white roll point, with point 8 being below Noordhoff's point on the vermilion–mucosal junction. Point 9 is made just above the cutaneous roll lateral to point 7. The distance between points 7 and 9 should equal the distance between points 2 and 4. Point 10 is placed medial to the alar insertion and meets point 5 at the height of the lip repair at the anterior nostril sill. Point 11 is positioned near the cleft margin at a distance from point 9 that is equal to the distance between points 3 and 4, and at a distance from point 10 that is equal to the distance between points 3 and 5. Source: Panossian & Fisher, 2008.⁸⁵ Reproduced with permission of Taylor & Francis.

4.5 mm wide between the bow peaks, and 6–8 mm in height (Figure 17.13). From the base of the prolabial flap at the lip–columella angle, the incisions pass superolaterally in a curvilinear fashion into each nostril sill. Noordhoff's point is marked on each lateral lip segment at the vermilion–cutaneous junction; in perpendicular orientation with the vermilion–cutaneous junction, and in alignment with Nordhoff's point, a supra-white roll point and a vermilion–mucosal junction point are marked. The incision along these three points is convex medially across the vermilion in order to replicate the median tubercle. A lateral back-cut is created from the supra-white roll point parallel with the vermilion–cutaneous junction, thus creating a cutaneous roll–vermillion flap whose geometry precisely corresponds to the caudal dimensions of the prolabial flap. Release of the lateral lip elements is performed via an upper lateral buccal sulcus incision in order to minimize the tension of the repair, with the soft tissues being freed from the underlying maxilla in a supra-periosteal plane such that the alar bases are completely mobilized. Aberrant insertions of the orbicularis oris muscle should be released from the lateral lip skin and the alar bases to allow descent of the cutaneous roll–vermillion flaps. The upper labial sulcus is recreated in a similar manner utilizing a prolabial mucosal flap. The inter-alar base width is reduced by means of an alar base cinch suture. A conservative primary rhinoplasty is advocated with the alar base

dissection extending cephalad in order to release the attachments of the alar–accessory cartilage complex from the lateral piriform margin. The nasal tip is not routinely dissected and internal nasal valve plication sutures are employed.

Primary nasal correction

The timing of nasal correction may be considered to be primary (concurrent with cheiloplasty), intermediate (during the school years) or secondary (once facial growth is complete). The concept of primary repositioning of the alar cartilages was advocated by McComb, who disproved the belief that manipulation of the nasal cartilages might adversely affect growth.^{86,87} The Tajima technique utilizes a reverse-U incision along the alar margin and redistributes the overhanging skin of the alar margin to augment deficient lining.⁸⁸ Open approaches, such as that described by Trott and Mohan, afford excellent visualization of the alar domes, but may compromise prolabial blood supply if adopted in complete bilateral cases, and carry a risk of nostril stenosis.⁸⁹ The goals of primary rhinoplasty include improving nasal contour, symmetry and nasal tip projection, with relocation of the caudal nasal septum. Primary rhinoplasty may reduce the complexity of a definitive secondary rhinoplasty procedure.⁹⁰ The potential risks of a primary rhinoplasty include iatrogenic deformity to the skin envelope and the introduction of scarring which may complicate subsequent interventions.

Nasal splints, such as the commercially available silicone Koken conformers, are frequently used after primary rhinoplasty as they are believed to maintain the nostril contour postoperatively, and may reduce the risk of relapse.^{91,92} Evidence for their efficacy is largely anecdotal. The optimal duration of treatment is much debated, ranging from 5 days to many months or more. Moreover, patient/parental compliance is essential and is typically the rate-limiting step for their continued use.

Postoperative care

The necessity for elbow restraints is much debated.⁹³ Our practice is for them to be worn for two weeks postoperatively. Children may resume oral feeding immediately in the recovery room following surgery. Most units discharge patients the following day, although day-case repairs are becoming increasingly common in selected patients.⁹⁴ If non-absorbable sutures are used, removal is undertaken on the 5th–7th postoperative day, often under sedation or general anaesthesia. Concerns regarding repeated anaesthetics on the neurocognitive development of children, a desire to minimize the burden of care in this patient cohort, and to rationalize healthcare resources, has resulted in the use of absorbable skin sutures becoming increasingly widespread.⁹⁵ Absorbable sutures may be associated with increased complications, including abscess formation or permanent suture marks, however, to date, the two closure methods have not been scientifically evaluated in the

setting of a randomized controlled trial. Significant variance exists with regard to the need for a postoperative dressing. The preference at The Hospital for Sick Children in Toronto is for topical bacitracin-polymyxin B ointment, which allows adequate wound toilet to prevent excessive crusting. The use of a Logan's bow to minimize tension across the lip repair is still practised in some centres.⁹⁶

Complications and revision surgery

Airway obstruction and anaesthetic complications are rare in otherwise healthy infants. Rare potential complications include bleeding, infection and wound dehiscence. A degree of scar contraction is inevitable, which will lead to a shortened lip at the three-month postoperative check. However, it invariably responds favourably to regular scar massage. Hypertrophic scars are less common, with keloid scars being extremely rare, even in darker skin types. Late inclusion dermoid cysts are occasionally seen.

Lip repairs performed with adherence to the defined principles are capable of producing reconstructions of excellent quality with minimal secondary deformity. Minor revisions, such as mucosal redundancy on the cleft side, can usually be deferred at least until the time of alveolar bone grafting. More significant deformities invariably warrant a complete lip revision. Timing is critical from the perspective of the child's psychosocial development; indeed the deformity may need addressing prior to commencing school. A secondary septorhinoplasty is commonplace in patients with a complete unilateral cleft lip and palate, and should be deferred until facial growth is complete.

Outcomes

Determining objective standardized outcome measures for cleft patients has been notoriously difficult to achieve. Indeed no international unanimity exists.⁹⁷ The 1992 Eurocleft study was the first international multicentre audit to compare treatment results in children with a unilateral cleft lip and palate.⁹⁸ Nasolabial aesthetics were assessed by a panel using cropped two-dimensional photographs, with significant differences in outcome noted between centres.⁹⁹ Limitations exist with still photographs, with video analysis essential for the assessment of dynamic facial appearance and the quality of orbicularis oris reconstruction. Three-dimensional imaging is an exciting adjunctive tool in aesthetic assessment. Quantitative measurement of nasolabial symmetry from two-dimensional photographs is now possible using SymNose software.¹⁰⁰ A universally agreed objective method of facial aesthetic assessment is vital if robust comparisons are to be made between centres.

The primary aim of cleft lip repair is to achieve a functional and aesthetically acceptable nasolabial appearance by minimizing the visible stigmata of the cleft-related deformity. However, the psychological status of cleft patients, in particular their socio-emo-

tional functioning, is critical for their ability to fully integrate into society and lead content and fulfilling lives. Cleft patients achieve a similar level of educational and vocational attainment as controls, although economic achievement may be less marked.¹⁰¹ Patients with cleft lip and palate have impaired psychological wellbeing with increased levels of anxiety and depression.¹⁰² Many avoid positions that expose them to direct public contact; cleft patients are less likely to marry, particularly those with a bilateral deformity. These issues highlight the importance of the clinical psychologist as an integral member of the cleft service.

Conclusion

In 1937 Kilner stated 'there is no branch of surgery that offers greater fascination than that which concerns itself with the repair of congenital clefts of the lip and palate, and none in which successful results give greater satisfaction.'⁹⁶ He acknowledged that surgeons shoulder a tremendous responsibility for treating these children, although to achieve results of the highest standard requires the collective effort of every member of the multidisciplinary team and a sound relationship with the child and their family.

²Department of Plastic Surgery, Great Ormond Street Hospital for Children NHS Trust, London, UK

Embryology

The primary and secondary palates arise from the frontonasal process and palatal processes of the maxilla, respectively, separated by the incisive foramen. From the incisive foramen, fusion of these processes occurs, progressing anteriorly during weeks 5–6 for the primary palate and posteriorly in weeks 7–8 for the secondary palate. Aberration of this process results in clefts between these embryologically distinct regions. More specifically, a cleft of the primary palate occurs between the premaxilla and ipsilateral palatal process of the maxilla, whereas a cleft of the secondary palate occurs between the two palatal shelves, with each shelf united to the premaxilla.

Cleft palate can occur in isolation or in combination with cleft lip, unilaterally or bilaterally. A cleft of the lip involving the primary palate terminates at the incisive foramen, in keeping with the embryologic origin of these structures as previously described. When a cleft of the lip and primary palate occurs in combination with a cleft of the secondary palate, the latter two malformations may be in continuity, resulting in the classic unilateral or bilateral cleft lip and palate, or discontinuous (for example, cleft lip and primary palate with cleft of the soft palate or incomplete cleft lip and complete cleft of the secondary palate) (Figure 18.1). An isolated cleft palate is subclassified as complete or incomplete, with the latter involving the soft palate with or without a portion of the posterior hard palate. In isolated cleft palate, the vomer is usually midline, vertically oriented and attached to the palatal shelves as far back as the anterior extent of the cleft. The vomer also maintains a vertical orientation in complete bilateral cleft lip and palate; however, may be laterally deviated contingent on the orientation of the premaxilla, from which the vomer projects. This is in contradistinction to the morphology of the vomer in unilateral cleft lip and palate, where the cranial portion of the vomer is almost vertical with angulation (often at 90°) of the caudal segment towards the

palatal shelf to which it is attached on the non-cleft side. The point of attachment between vomer and palatal shelf can be discerned by the colour variance of nasal and oral mucosa, respectively.

Isolated cleft palate is epidemiologically and aetiologically distinct from cleft lip and palate. The incidence of cleft lip and palate varies by race, with approximately 2 in 1000 in East Asian populations, 1 in 1000 in white populations and 0.4 in 1000 in black populations. Moreover, males are twice as likely to be affected than females. In contrast, isolated cleft palate occurs in 1 in 500 live births across all ethnic backgrounds and more commonly in females, with a 2:1 predominance over males. Of all orofacial clefts, approximately 20% are isolated cleft lips, 35% isolated cleft palates, and 45% are clefts involving lip and palate. The aetiology of clefting is multifactorial, including genetic factors, environmental factors and gene–environment interactions. Environmental risk factors include maternal obesity, diabetes mellitus, exposure to alcohol, smoke, diet, viral infections, drugs and various teratogenic agents, as well as physical and/or emotional stress. A strong association between the *interferon regulatory factor 6* (*IRF6*) gene and non-syndromic cleft lip and palate has been demonstrated. It has been reported that aberrations of *IRF6* comprise 12% of the genetic contribution to cleft lip and palate and increase the risk of recurrence three-fold in families with one affected child.¹ The familial association for cleft palate is commonly cited as follows:²

- If normal parents have a child with cleft palate, the frequency of cleft palate in the next child is estimated at 2%.
- If normal parents with a family history of cleft palate have a child with cleft palate, the risk for the next child is 7%.
- If normal parents have two children with cleft palate, the risk for the next child is 1%.
- If one parent has a cleft palate and no previously affected children, the risk for the next child is approximately 6%.
- If one parent has a cleft palate and a child with cleft palate, the risk for the next child is 15%.

Anatomy

The hard palate is composed of palatine processes of the maxilla and the palatine bone. The palate is supplied by the greater palatine vessels and nerves, which emerge through the greater palatine foramina in the postero-lateral regions of the hard palate. The nasal mucosa of the hard palate is in continuity with the mucosa of the lateral nasal walls, and medially with the vomerine mucosa. The soft palate is the mobile palatal segment, with muscles that act synergistically to effect velopharyngeal closure. The sensory supply of the soft palate is derived primarily from the lesser palatine nerves, which are comprised of several branches that extend from the lesser palatine foramina in the palatal processes of the sphenoid through the palatal aponeurosis.

From a functional perspective, the *levator veli palatini* is considered the most important muscle of the soft palate. This muscle originates from the petrous temporal bone and the junction of bony and cartilaginous portions of the Eustachian tube. It then courses inferiorly, anteriorly and medially to enter the velum and join the levator from the opposite side, forming the *levator sling*. The levator is found in the middle third (40%) of the velum,³ between the two heads of the palatopharyngeus⁴

Figure 18.2 A nasal view of dissected soft palate musculature, demonstrating the position of the levator veli palatini, which occupies the intermediate 40% of the soft palatal length. Source: Boorman & Sommerlad, 1985.³ Reproduced with permission of Elsevier.

(Figure 18.2). The levator is innervated by the pharyngeal plexus (motor branches of the ninth, tenth and eleventh cranial nerves). Moreover, it has been suggested that the muscle also receives innervation from the seventh cranial nerve. This is supported by findings of hemi-palatal palsy in patients with hemifacial microsomia.⁵ The cumulative action of the levator is to pull the velum superiorly and posteriorly. In the cleft palate, the levator inserts into the cleft margin in the anterior half of the velum and *not directly into the posterior edge of the hard palate*, as is commonly cited.⁶

The palatopharyngeus originates from the palatine aponeurosis, and then divides into vertical and transverse fibres. The vertical fibres, palatopharyngeus, form the posterior faucial (tonsillar) pillars, course in the lateral pharyngeal walls and insert into the greater horns of the thyroid cartilage of the larynx. The transverse component, palatopharyngeus proper, courses posteriorly along the lateral pharyngeal walls and intermingles with the superior pharyngeal constrictor muscle. The palatopharyngeus is also innervated by the pharyngeal plexus. Although most of the literature supports the notion that the palatopharyngeus is more active during swallowing than speech, the palatopharyngeus fibres are in an anatomical position to act as an antagonist to the elevating action of the levator muscle but as a synergist in stretching the velum backwards. The palatopharyngeus proper assists in the medial displacement of the lateral pharyngeal walls during velopharyngeal closure and contributes to the formation of *Passavant's ridge*. Further, muscular contraction of the palatopharyngeus stretches the velum inferiorly and laterally to increase the available velar surface area and optimize velar shape for contact with the posterior pharyngeal wall. In the midline of the cleft palate, the levator and palatopharyngeus fuse to form the 'cleft muscle' as described by Veau.⁷ However, in contradistinction to the levator veli palatini, the palatopharyngeus also inserts into the posterior border of the hard palate.

The palatoglossus is the most superficial (oral) muscle of the soft palate, traverses through the anterior tonsillar pillars and inserts into the tongue. As such, contraction results in tongue elevation, palatal depression and narrowing of the pharyngo-oral isthmus. The muscle does not have an ascribed role in velopharyngeal closure per se. The levator, palatopharyngeus and palatoglossus diverge anteriorly to insert into the margins of the cleft, aberrant palatal aponeurosis, as well as the oral and nasal mucosa.

The superior pharyngeal constrictor is a quadrangular muscle, which originates from the medial pterygoid plates and pterygomandibular raphe. The muscle courses around the pharynx, forming the lateral and posterior pharyngeal walls, enclosing the nasopharynx and upper oropharynx. The muscle fibres diverge superiorly and inferiorly as they approach the posterior midline to insert into the pharyngeal ligament. The space between the superior margin of the muscle and cranial base is occupied in the lateral nasopharyngeal wall by levator and Eustachian tube and in the posterior pharyngeal wall by the pharyngobasilar fascia. The muscle, innervated by the tenth cranial nerve, causes medial excursion of the lateral pharyngeal walls and, along with palatopharyngeus, anterior displacement of the posterior pharyngeal wall. The latter accounts

for the formation of *Passavant's ridge*. Although historically considered a compensatory mechanism in patients with velopharyngeal insufficiency (VPI),⁸ much evidence exists to challenge this assertion.⁹ For instance, the ridge is often noted to be below and slower than palatal excursion.

The tensor veli palatini does not contribute to movement of the velum. The tensor originates from the scaphoid fossa of the greater wing of the sphenoid and membranous portion of the Eustachian tube. The muscle courses medially and inferiorly parallel to the levator and forms a tendon. The tendon hooks around the hamulus of the pterygoid plate (to which it is partially attached), assumes a horizontal orientation and inserts along the posterior border of the hard palate as the palatal aponeurosis, occupying the anterior third of the velum. In the cleft palate, the tensor palatini reaches the hamulus and appears to diverge into two components – a triangular tendinous portion, which inserts into the lateral posterior edge of the hard palate (does not form the palatal aponeurosis), in close proximity to the nasal mucosa, and a less substantial component, which passes towards the oral surface behind the greater palatine neurovascular bundle. Some authorities recognize a separate but closely related muscle, the dilator tubae, which rounds the middle third of the pterygoid hamulus without an insertion. There has been much debate as to whether the tensor (and/or dilator tubae), have a significant action on the velum and regarding the relative importance of the tensor (and/or dilator tubae) and levator in Eustachian tube function.

The musculus uvulae, thought to be supplied by the lesser palatine nerve, is a paired muscle located above the levator, attached to the palatal aponeurosis anteriorly and passing into the uvula posteriorly. The muscle is covered nasally and laterally by mucous glands. Contraction of the muscle may assist in velopharyngeal closure by adding to the bulk of the midline dorsal ridge over the levator eminence and also possibly by lifting the free border of the palate into deeper contact with the posterior

pharyngeal wall.¹⁰ Others argue that this muscle may not be of importance in velopharyngeal function.¹¹ In the cleft palate, the presence of the musculus uvulae is controversial and rarely seen.

Finally, the salpingopharyngeus is a small muscle that originates from the torus tubarius and courses vertically along the lateral pharyngeal walls. Although this muscle does not contribute to velopharyngeal closure, it may draw the lateral pharyngeal walls superiorly.

Submucous cleft palate

Submucous cleft palate is a form of cleft palate wherein the mucosa is intact but the underlying musculature is similarly abnormal to that of an overt cleft palate. In 1954, Calnan¹² qualified the overt submucous cleft palate with a *classic triad*, including bifid uvula, palpable notch in the posterior hard palate and zona pellucidum. The zona pellucidum is a midline translucent zone that represents diastasis of the velar musculature (Figure 18.3). Kaplan¹³ described the *occult* submucous cleft palate, where velar malfunction is observed, but the aforementioned or typical features are not apparent. Given evidence of velopharyngeal dysfunction (VPD), the diagnosis of occult submucous cleft palate is often made following evaluation with nasopharyngoscopy, where a midline groove or concavity is seen on the nasal surface of the palate. The latter is thought to represent hypoplasia or agenesis of the musculus uvulae, as well as velar musculature diastasis.¹⁴ Sommerlad *et al.*¹⁵ argued that there is a spectrum of severity in submucous clefting and described a scoring system based on the severity of each feature of the triad. In effect, Kaplan¹³ postulated that isolated clefts of the secondary palate, overt and occult submucous cleft palates are variations in expression of the same embryonic process. Diagnosis of submucous cleft palate is often delayed until speech development allows appreciation of VPD.

(a)

(b)

Figure 18.3 Clinical images of an overt submucous cleft palate, demonstrating the zona pellucidum and bifid uvula.

Associated syndromes

Although a syndrome occurs in approximately 10% of patients with cleft palate in association with cleft lip, associated syndromes are described in up to 50% of cases with isolated cleft palate.

Pierre Robin sequence

The most commonly associated anomaly is Pierre Robin sequence, which occurs in approximately 1 in 8500–14000 births. The condition typically occurs sporadically, but may be familial, with autosomal dominant mode of inheritance. The sequence includes micrognathia/retrognathia, glossoptosis and respiratory distress.¹⁶ Although not a qualification of the sequence, a cleft palate occurs in approximately 60–90% of cases. Indeed, in his original description of 1923, Pierre Robin, the French stomatologist credited for the identification of these

infants, failed to include cleft palate as an associated feature, but later added cleft palate as an aggravating factor.¹⁷ The cleft palate in the context of Robin sequence is typically U-shaped, as opposed to the classic V-shaped cleft palate, and implies a wider palatal gap. The theory for the occurrence of cleft palate in Robin sequence is that the posterior displacement of the mandible results in elevation and dorsiflexion of the tongue at approximately 9 weeks of gestation, preventing migration and fusion of the palatal shelves. The majority of cases (83%) present as a component of a named syndrome, including Stickler syndrome, velocardiofacial syndrome, Treacher Collins syndrome, fetal alcohol syndrome, Nager syndrome, oculo-auriculo-vertebral spectrum, Apert syndrome, ectrodactyly-ectodermal dysplasia clefting syndrome, Opitz-G/BBB syndrome and orofacial digital syndrome. Thus, with the Robin sequence, the presence of other anomalous features should be considered (Figure 18.4).

Figure 18.4 Lateral photographs of infants with Pierre Robin sequence. (a) Non-syndromic infant with severe micrognathia, nasopharyngeal airway and gavage tube in place. (b) Typical U-shaped cleft palate. (c, d) Infant with Robin sequence and hemifacial microsomia. (e) In this case, there is a cleft of the soft palate only.

The glossoptosis in Robin sequence initiates a sequence of events including airway obstruction, increased energy expenditure and impaired caloric intake from poor feeding. Thus, in the neonatal period, the primary objectives are to relieve airway obstruction and avert failure to thrive. However, glossoptosis is not the only contributor to upper airway obstruction in children presenting with Robin sequence. Acute angulation of the basicranium, pharyngeal, laryngeal and/or lingual anomalies, subglottic anomalies, hypotonia and CNS disorders may all cause or contribute to airway obstruction.¹⁸ Thus, microlaryngobronchoscopy is essential to determine the mechanism(s) of airway collapse and if obstruction can be relieved completely with treatment strategies that address tongue positioning alone.

In effect, Sher *et al.*,¹⁹ based on endoscopic observations, demonstrated four patterns of pharyngeal collapse in patients with craniofacial anomalies, any of which can be found in Robin sequence.²⁰ In types 1 and 2, the retro-positioned tongue is the primary aetiological factor responsible for obstruction, whereas in types 3 and 4 airway compromise is secondary to lateral pharyngeal wall collapse and pharyngeal stenosis, respectively. Thus, no single treatment will resolve respiratory obstruction in all patients, and management must be tailored to the specific underlying aetiology. Airway compromise is assessed with oxygen saturation recordings and polysomnographic studies, the need for oxygen supplementation and appropriate weight gain (with or without gavage feeding). Routine laboratory investigations and additional studies include serial blood gas analysis for elevated levels of carbon dioxide and serum bicarbonate, and pH recording for gastroesophageal reflux. As primary measures, management of airway compromise secondary to *glossoptosis* include prone or semi-prone positioning and placement of a nasopharyngeal airway with or without continuous positive airway pressure. If the latter conservative treatment modalities fail to relieve airway

obstruction, surgical intervention is warranted. Douglas²¹ popularized the technique of glossopexy, originally described by Shukowsky in 1911.²² This procedure was later modified by Routledge²³ and various modifications were subsequently developed. The latter concept is based on the premise that airway obstruction is secondary to glossoptosis and surgical adhesion between tongue and lip can effectively mitigate the retro-displacement of the tongue. In 1983 a French stomatologist, Viviane Epou, ²⁴ asserted that the imbalance of the muscular insertion of the tongue on the mandible was responsible for the micrognathia, tongue elevation and glossoptosis. More specifically, that the musculature of the floor of the mouth is under increased tension and impels the tongue superiorly and posteriorly, resulting in respiratory obstruction. The latter is the premise for the subperiosteal release of the floor of the mouth musculature for refractory cases of respiratory obstruction in the Robin anomalad.^{25,26} Following release, the tongue can adopt a more anterior position. Mandibular distraction is now a well recognized and widely used surgical alternative in patients with obstruction refractory to conservative measures. With this method the tongue is indirectly pulled forward through muscular attachment to the lingual surface of the mandible.²⁷ In instances where the latter measures fail or in cases where other airway anomalies contribute to obstruction, tracheostomy is often required.

Stickler syndrome

Stickler syndrome is a hereditary progressive arthropathopathy with a estimated frequency of 1 in 10000. It is an autosomal dominant connective tissue dysplasia characterized by cleft palate, degenerative joint changes, ocular manifestations and progressive sensorineural hearing loss. Moreover, these patients often exhibit a characteristic flat facial appearance, secondary to hypoplasia of the mid-face and bridge of the nose (Figure 18.5).

Figure 18.5 Clinical images of infant with Stickler syndrome. Note the facial features characteristic of this syndrome, including prominent eyes, flat nasal bridge, anteverted nares and mid-face hypoplasia.

van der Woude syndrome

Although rare (1 in 100 000), van der Woude syndrome is an autosomal dominant syndrome with variable expressivity also associated with cleft palate. Van der Woude syndrome is associated with *IRF6* gene mutations on chromosome 1q. Moreover, it is unique in that it may also be expressed as either cleft lip with or without cleft palate. A distinguishing feature of the syndrome is bilateral para-median lower lip pits. *IRF6* mutations are also responsible for the popliteal pterygium syndrome, which is characterized by cleft lip and/or palate, lower lip pits and additionally qualified by the presence of bilateral popliteal webs, hypodontia, syndactyly, nail abnormalities, anomalies of the genitourinary system and ankyloblepharon. Interestingly, as previously mentioned, the *IRF6* gene has been recognized to have the strongest genetic association with non-syndromic cleft lip and palate. Indeed, some patients with van der Woude syndrome do not display the typical lower lip pits, and may be erroneously classified as non-syndromic. Thus, *IRF6* gene mutations should be considered in those with affected parent-child and especially segregating cleft palate and cleft lip and palate.²⁸

22q11.2 deletion (velocardiofacial) syndrome

Although clinically underrecognized, velocardiofacial syndrome (VCFS) is the most common multiple anomaly syndromes in humans, with an estimated frequency of 1 in 2000–4000 live births and equal sex distribution. Microdeletions occur in the q11.2 region of chromosome 22, identified by fluorescence *in situ* hybridization (FISH) test. In these patients, the *TBX1* gene is always deleted, with 90% of patients having a deletion of the typical deleted region (TDR; common 22q11.2 deletion, size 3 Mb), while 10% have a smaller deletion of only the proximal 1.5 Mb of the TDR (proximal deleted region, PDR). Both TDR and PDR include the *TBX1* gene area. A few individuals with VCFS have shown unique 22q11.2 deletion intervals or a chromosome

10p14 deletion. In the majority of patients (>90%) 22q11.2 deletions occur as spontaneous events, with both parents unaffected. However, in approximately 10% of individuals, deletion is identified in a parent and thus there is autosomal dominant transmission with variable expression.

There is phenotypic overlap between VCFS and DiGeorge, Sedlacková, conotruncal anomaly face and Cayler syndromes. Indeed, all these aforementioned syndromes are descriptions of the same entity, with over 180 separate anomalies or developmental sequences reported in association with VCFS covering nearly every organ and system. Notable among these are immune deficiency, hypocalcaemia, conotruncal cardiac anomalies, short stature, learning difficulties, behavioural problems, psychiatric illnesses and slender hands and digits. These patients also have a characteristic facial appearance, due to a combination of skeletal and soft tissue features. These include microcephaly, a long middle third of the face, flat zygomatic arches, mandibular retrognathia, broad nasal dorsum, narrow alar bases and bulbous nasal tip, hypotonic flaccid facies, narrow, down-slanting palpebral fissures, and external ear anomalies (Figure 18.6). Also reported in patients with VCFS are aberrant carotid and subclavian arteries. Indeed, it has been hypothesized that the large number of vascular anomalies in major vessels reported in patients with VCFS may result in a number of developmental sequences. The latter notion is supported by reports of Robin, DiGeorge, Potter and holoprosencephaly sequences in individuals with VCFS. The phenotypic expression in this syndrome is markedly variable with no clinical feature occurring in all cases and no reported case with all or even most of the associated clinical findings.²⁹

VCFS is now recognized as the most common syndrome associated with cleft palate and velopharyngeal insufficiency. The majority (approximately 75%) of children with VCFS have hypernasal speech and severe language impairment. Moreover,

Figure 18.6 Clinical images of children with facies characteristic of velocardiofacial syndrome.

affected individuals commonly present with VPI, most often associated with overt or occult submucous cleft palate. While the frequency of VPI among individuals with non-syndromic submucous cleft palate is approximately <9%, VCFS patients show VPI associated with submucous cleft palate in >70% of cases. In addition to overt or occult submucous cleft palate, there are several other factors that contribute to the high frequency of VPI in VCFS, including platybasia, congenitally short velum, palatopharyngeal disproportion, abnormalities of pharyngeal muscles with hypodynamic velopharynx, lymphoid tissue (adenoid) hypoplasia, and tonsillar hypertrophy. The latter anatomic and physiologic anomalies often render management of VPD in patients with VCFS a greater therapeutic challenge than in their non-syndromic counterparts, often necessitating a combination of palatoplasty and pharyngeal surgery. Despite the more extensive surgical correction required, speech outcomes are universally inferior when compared with those for non-syndromic patients.

Palatoplasty

Pathologic sequelae of cleft palate include feeding and nutritional difficulties, serous otitis media (with potential hearing loss) and abnormal speech development. Thus, the goals of cleft palate repair include improved feeding and normal speech, while minimizing the deleterious impact on maxillary growth and dental arch relationship.

In the neonatal period, feeding and adequate weight gain are a priority. Due to reduced ability to suck, and particularly to draw the nipple into the mouth, infants with cleft palate have difficulty feeding, and breastfeeding can only be achieved with considerable effort and modification of technique. In developed countries, most infants are bottle-fed, which allows a steady stream of milk, usually by a modified teat and soft bottle.

With regards to hearing, all patients with cleft palate should undergo a neonatal hearing assessment. Some argue that ventilation tubes should be inserted if there is a persistent conductive hearing loss of >45 dB on distraction testing or >35 dB on pure tone audiometry. However, given there is evidence that correction of the muscle abnormality in the cleft palate improves Eustachian tube function, others contend that insertion of ventilation tubes should be deferred.

Children with clefts generally do not have difficulties with swallowing and aspiration unless there is a coexisting intrinsic neuromuscular or anatomic abnormality of the tongue or pharynx. Evidence of the latter usually warrants further investigation with videofluoroscopy and endoscopy.

Timing of repair

There is little debate that, in most situations, a cleft palate should be repaired. However, consensus is lacking on timing of repair. Restricted maxillary growth secondary to cleft palate repair has prompted some to promote two-stage palatoplasty, wherein the velum is repaired early in order to enable normal speech

acquisition and hard palate closure delayed to facilitate maxillary development.³⁰ Delayed closure of the hard palate may benefit facial growth but most reports suggest detrimental effects on speech.³¹ Irrespective, there is general agreement that soft palate repair should be effected before 12 months of age. The senior author aims to achieve complete palate closure by 6 months of age. There is evidence from a randomized controlled trial that speech outcome is superior following palatoplasty at 6 months as compared to 12 months.³² In this study, children with clefts repaired at 6 months of age did not develop compensatory articulations, while those with palate repair delayed to 12 months of age did display abnormal articulation patterns. Further, no difference in maxillary arch development, soft tissue profile or velopharyngeal dysfunction was noted between the two groups at 4 years from surgery. There is currently an international randomized controlled trial, the Timing of Primary Surgery for Cleft Palate (TOPS trial) comparing palate closure at 6 and 12 months of age.

For submucous cleft palate repair, timing is similar to overt cleft palate repair for infants with obvious evidence of a submucous cleft and persistent feeding difficulties. Where feeding is not a considerable issue, repair is otherwise indicated if an infant is not producing pressure consonants (/d/, /b/) by 15–18 months. In the older child with submucous cleft palate, surgical treatment is *indicated only in the presence of consistent VPI* or persistent hypernasality, as the presence of submucous cleft palate does not ensure VPD.

Preoperative assessment

Appropriate preoperative assessment is mandatory to ensure that there is no history of airway compromise or anaemia and there is adequate weight gain. The main contraindications to palate repair are associated medial co-morbidities, which may present an unacceptable increased anaesthetic risk and sub-optimal weight.

Controversy exists regarding the benefits of palate repair in older children and adults. Arguably, adults with unrepaired clefts have compensatory patterns of articulation that are so well embedded that palate repair is unlikely to make much difference to speech. However, there are reports of some improvement in speech even though normality is not achieved. An international task force has produced a report and recommendations on delayed palate repair.³³

History of palatoplasty

In 1859, Bernhard von Langenbeck described bilateral bi-pedicled mucoperiosteal flaps for palate repair.³⁴ Lateral relaxing incisions are made at the junction of gingival and oral palatal mucoperiosteum lateral to the greater palatine neurovascular bundle, in addition to cleft marginal incisions (Figure 18.7a). Further developments in technique by Victor Veau,³⁵ Thomas Kilner³⁶ and William Wardill³⁷ were introduced to increase palatal length in an effort to aid in velopharyngeal closure. The three- or four-flap Veau–Wardill–Kilner push-back palatoplasty

includes a V to Y incision and closure of the anterior hard palate (Figure 18.7b). The resulting flaps are based on the greater palatine arteries posteriorly. Inherent in the push-back operation is release of the muscular attachments from the posterior edge of the hard palate. Although the push-back palatoplasty lengthens the palate, theoretically retro-positioning the levator into a more favourable position, this has *not* been shown to be effective in improving speech. Moreover, by virtue of the fact that the bone is denuded anteriorly, this repair adversely affects maxillary growth and the single nasal mucosal layer anteriorly is associated with a higher rate of fistula. In effect, the latter procedure has been largely abandoned in modern era palatoplasty. The two-flap technique popularized by Janusz Bardach³⁸ does not aim to achieve push-back, but is believed by its proponents to improve exposure of the underlying velar musculature (Figure 18.7c). Many surgeons simply return the flaps to their original position to avoid leaving raw areas of bone. Arguably, this may not avoid impairment of maxillary growth.

In the early twentieth century, Victor Veau⁷ first described the anomalous cleft musculature and promoted the concept of suture approximation of the levator in a side-to-side fashion without any endeavour to address the aberrantly positioned muscle. Braithwaite³⁹ and Kriens⁴⁰ emphasized restoration of the *levator sling* by dissection of the abnormally positioned levator muscles prior to re-approximation. Edgerton and Dellon⁴¹ suggested that following dissection, the levator bundles should be rolled 180° and sutured to the musculus uvulae near the uvular base. The double opposing Z-plasty technique, described in 1978 and later published in 1986 by Leonard T. Furlow Jr,⁴² is often used for the primary repair of isolated clefts of the soft palate or submucous cleft palate, or as a secondary technique to lengthen the previously repaired palate. With this technique, 60° Z-plasties are outlined on both oral and nasal mucosa in opposite directions with the central limb placed along the cleft margin. The posteriorly based flap on each surface is composed of muscle (levator) and mucosa, and the anterior flap of mucosa

only (Figure 18.8). Possible advantages of this procedure include lengthening, increased vascularization of the muscle and technical facility. Disadvantages are lateral tightening by Z-plasty closure, less anatomic reconstruction of the musculature, asymmetric velar excursion and difficult closure with wide clefts. Cutting⁴³ and Sommerlad⁴⁴ advocated more extensive dissection of the levator muscles and radical retro-positioning of the velar musculature in their respective techniques of intravelar veloplasty. In an effort to facilitate closure, von Langenbeck incisions are often combined with Furlow's palatoplasty or radical intravelar veloplasty for palate repair.

There are several different protocols and techniques for repair, with variable sequences for closure of the lip, alveolus, hard and soft palates. In the senior author's practice, the operating microscope has been used for palate repair since 1991.⁴⁵ In clefts of the lip and palate, since 1993, a single layer vomerine mucoperiosteal flap has been used for closure of the hard palate and nasal floor at the time of lip repair at three months of age. The vomer flap was first introduced by Pichler in 1926⁴⁶ and was originally described as an inferiorly based flap. This flap resulted in significant maxillary retrusion, presumably secondary to injury to the vomerine-premaxillary suture. However, long-term studies of the superiorly based vomerine flap have not demonstrated a similar deleterious effect on maxillary growth, probably due to the relatively more limited dissection.^{47,48} In the case of unilateral cleft lip and palate, an incision is made at the junction of palatal and vomerine mucosa on the non-cleft side, extending posteriorly down the crest of the vomer and anteriorly around the side of the premaxilla to become continuous with the medial lip incision. The oral mucoperiosteum is incised along the margin of the cleft and elevated to allow the vomerine flap to be inserted underneath. In bilateral cleft lip and palate, one vomerine flap is elevated as previously described. As complete elevation of bilateral vomerine flaps may jeopardize the blood supply of the premaxilla and prolabium, the flap on the other side is elevated only to the pre-vomerine suture. In the interim period between cleft lip and anterior palate repair and soft palate repair, the exposed periosteal surface of the vomerine flap epithelializes to create an intact hard palate.

Sommerlad technique for palate repair

A modified mouth gag is inserted followed by a gauze throat pack. The junction of the oral and nasal mucosa is marked with ink (Figure 18.9a). The nasal mucosa is usually on the oral side of the edge of the cleft and darker than the oral mucosa (Figure 18.9b). The palate is infiltrated with lidocaine (lignocaine) with adrenaline (epinephrine) and the palate incised along the margin of the cleft at the junction of oral and nasal mucosa. The incision then extends from the midline at the anterior limit of the cleft anteriorly onto the posterior border of the hard palate to enable subperiosteal elevation of the oral mucoperiosteal flaps to expose the bony palatal shelves (Figure 18.9c). Dimples are frequently seen on the oral side of the palate at a

point where oral mucous glands are attached to the posterior border of the hard palate and tendinous nasal component of tensor palatini. Care must be taken to elevate these mucous glands intact with the oral flap (Figure 18.9d). Dissection is facilitated with the use of a dental scaler or Freer's elevator.

In wide clefts, where more extensive mobilization of the oral layer is necessary, dissection extends laterally to free the greater palatine neurovascular bundle, with incision of its surrounding periosteal sleeve when necessary. Elevation of the oral layer is continued posteriorly into the soft palate and laterally to the pterygoid hamulus, separating the oral mucosa and attached mucous glands from the underlying musculature, the palatopharyngeus and palatoglossus. The nasal mucosa is mobilized from the nasal surface of the palatal shelves, if necessary, and sutured in the midline. For soft palate closure in patients with unilateral or bilateral cleft lip and palate, in whom a vomerine flap was used for closure of the hard palate at the time of unilateral or bilateral lip repair, a posteriorly based flap of the neomucosa from the epithelialized vomer may be raised and turned back to facilitate closure of the anterior nasal layer of the soft palate (Figure 18.9e,f). Following closure of the nasal layer, the anteriorly oriented muscle fibres are seen inserting into the posterior border of the hard palate (Figure 18.9g). For muscle dissection, an incision is started posteriorly approximately 4 mm from the midline and is extended anteriorly closer to the midline, just lateral to the nasal layer sutures, leaving the mucous glands in place centrally. The palatopharyngeus medially and the nasal component of the tensor tendon laterally are divided from the back of the hard palate and dissection proceeds in a plane between nasal mucosa and musculature. Vessels are seen on the nasal mucosa and are preserved where possible. The tensor tendon is then divided in an anteroposterior direction medial to the hamulus. The oral palatoglossus and palatopharyngeus fibres are then split to expose the levator, which is identified as a discrete cylindrical muscle within a defined fascial envelope (Figure 18.9h), and is paler than the other palatal muscles.

Dissection is continued until the muscle can be transposed to the posterior half of the velum. A stab incision is made in the nasal mucosa on each side, if a hole was not inadvertently created during muscle dissection. The latter permits draining in an effort to prevent haematoma formation. The levators are then united along with retro-displaced palatopharyngeus and tensor tendon, which imparts strength to the repair (Figure 18.9i). Finally, the oral layer is closed (Figure 18.9j,k). First, one or two sutures are placed in the midline anterior to the muscle repair between oral mucosa and the nasal mucous glands. The latter occludes the dead space and assists in maintaining the muscle retro-positioned. The oral layer is closed with a twisted loop mattress stitch.⁴⁹

For repair of submucous cleft palate, a similar technique is used as described above, leaving the nasal layer intact and leaving, if possible, some mucous glands on the nasal layer in the midline.

The senior author aims to achieve velar closure without lateral releasing incisions (von Langenbeck). The need for lateral releasing incisions depends on the type, extent and width of the cleft. Lateral releasing incisions are most often required in patients with Robin sequence with a wide U-shaped cleft, and anticipated if the width of the cleft at the back of the hard palate is in excess of 10 mm at an age of repair of six months. Hard palate closure without lateral releasing incisions depends on the 'drawbridge effect' (where the sloping high-arched oral mucoperiosteal flaps are brought into greater proximity when mobilized into horizontal position), unfolding of the infolded areas of the flaps and division of the oral component of the tensor palatini insertion and/or the periosteal sleeve of the greater palatine neurovascular bundle.

Repair of submucous cleft palate

In patients with submucous cleft palate, the extent of morphologic abnormality is not in direct proportion to the size of the velopharyngeal gap or severity of hypernasality. As previously mentioned, the latter is secondary to compensatory factors including prominent adenoid pad and/or significant excursion

of the pharyngeal musculature.⁵⁰ The authors' approach to the treatment of VPI in patients with submucous cleft palate is to optimize levator function with a radical dissection and retro-positioning of the abnormally positioned velar muscles. Upon palate exploration, if the levators are deemed to be in a satisfactory location, then management favours a Hynes pharyngoplasty to augment the posterior pharyngeal wall.⁵¹ Following reassessment at six months postoperative follow-up, the necessity for further surgery is determined. The latter may be either a modified Hynes pharyngoplasty or buccinator flap lengthening of the palate.

Complications of palatoplasty

The complications commonly associated with cleft palate repair include acute airway obstruction, bleeding, infection and partial or complete palatal dehiscence. The latter may result in fistula formation. Treatment of problematic fistulas depends on location and size. Associated symptomatology includes nasal regurgitation, as well as hypernasality and other manifestations of VPI. Corrective measures include repair with local mobilization of nasal and oral palatal tissue, with or without placement of

interpositional tissue or material, such as a segment of pedicled buccal fat pad, cartilage graft or acellular dermal matrix, or formal palate re-repair. Other options include regional flaps (buccal mucosal or musculomucosal flaps, facial artery myomucosal flap, tongue flap) and rarely, free tissue transfer. When circumstances preclude surgical correction, an obturator can be utilized. Potential long-term sequelae of palatoplasty include maxillary retrusion and, most notably, VPI.

Velopharyngeal dysfunction

The function of the velopharyngeal mechanism, which consists of the velum, lateral and posterior pharyngeal walls, is to separate the oro- and nasopharynx during speech and deglutition. Normal velopharyngeal closure is necessary for proper consonant production and nasal resonance. In the English language, only three sound /m/, /n/ and /ng/ do not require closure. The primary manifestations of ineffective closure of the velopharyngeal port are excessive nasal resonance or hypernasality and nasal air emission. Hypernasality results from abnormal coupling of the oral and nasal cavities during vowel production and nasal air emission is noted with consonant production.

Some authors have attempted to distinguish between *velopharyngeal insufficiency*, *incompetence* and *dysfunction*. Velopharyngeal *insufficiency* refers to hypernasality and nasal air emission during speech secondary to anatomic aberration of the velopharyngeal sphincter. In contrast, velopharyngeal *incompetence* is employed to describe dysfunction of an anatomically intact velopharyngeal mechanism, usually secondary to neuromuscular discoordination. Finally, velopharyngeal *dysfunction* is a term used to describe all conditions that affect velopharyngeal closure, such that the valve does not achieve consistent and/or complete closure during oral sound production.

Irrespective of the nature of the VPD, in an attempt to overcome the inability to achieve velopharyngeal closure, children develop compensatory patterns of articulation (e.g. pharyngeal or nasal fricatives and glottal stops) and other secondary speech patterns, including hoarseness and low speech volume, which can significantly compromise speech intelligibility. Moreover, children may display behavioural idiosyncrasies such as nasal or facial grimace in an attempt to decrease nasal airflow. Causes of VPI include repaired cleft palate, palatal fistula, submucous cleft palate, maxillary advancement, congenital large pharynx or palatopharyngeal disproportion, adenoid regression, irregular adenoid pad and/or adenoidectomy. The influence of the adenoids on velopharyngeal closure, merits more detailed description.⁵² Most children exhibit velo-adenoidal closure where the soft palate abuts the adenoid pad, which is positioned on the posterior pharyngeal wall in the area of usual velar contact. Although adenoid regression does not affect velopharyngeal closure in children with a normal velum, in those with a previously repaired cleft palate, overt or occult submucous cleft palate, evidence or deterioration of existent VPI may be noted. In like manner,

hypernasality or nasal air emission may occur following adenoidectomy in patients with no velar defect, but does not typically persist for more than six weeks postoperatively. Enduring VPI has been reported to occur in approximately 1 in 1500, more likely in patients with overt or occult submucous cleft palate, where removal of the space-occupying adenoids unmasks underlying palatal deficiency.

Finally, in some patients, the shape of the adenoid tissue may in fact be detrimental to closure, wherein irregular surface morphology prevents a tight velopharyngeal seal. Velopharyngeal incompetence can occur in patients with generalized hypotonia (e.g. VCFS), neurological conditions causing dysarthria (e.g. myotonic dystrophy, cerebral palsy, neurofibromatosis, Steinart's syndrome) or apraxia and cranial nerve defects (e.g. hemifacial microsomia).

Assessment of velopharyngeal function

Selection of the appropriate procedure for correction of VPD is based on speech evaluation by a trained speech and language therapist, direct physical examination of the palate, as well as instrumental assessment. On intra-oral examination, static and dynamic palatal evaluation is assessed. Inspection for features of submucous cleft palate, as well as presence of palatal fistula and tonsillar hypertrophy is completed. Normally during production of 'ah', presence of a simple midline palatal dimple is seen at the junction of the middle and posterior thirds of the soft palate. Presence of two lateral dimples, a single unilateral or complete absence of the dimple, as well as an anteriorly displaced dimple are indicative of abnormal levator muscle insertion and functional compromise.²

Nasoendoscopy allows direct visualization of the velopharyngeal mechanism from both anatomic and functional standpoints. With nasoendoscopy, the contribution of the velum, lateral and posterior pharyngeal walls (i.e. closure pattern) can be assessed, and in the presence of VPD, the size and location of the velopharyngeal gap as well as timing of velopharyngeal closure can be measured. Hypernasality is not necessarily related to the size of the velopharyngeal gap. Patients with a small velopharyngeal gap may present with severe hypernasality due to delayed time of velopharyngeal closure during speech. Velopharyngeal closure patterns, originally described by Skolnick *et al.*⁵³ and Croft *et al.*,⁵⁴ include coronal, sagittal, circular and circular with Passavant's ridge. The most common pattern is coronal, where the velum approximates the posterior pharyngeal wall, while the lateral pharyngeal walls move medially to abut the lateral edges of the velum. In sagittal closure pattern, velopharyngeal competence is primarily a function of the lateral pharyngeal walls, which move medially posterior to the velum with the velum approximating the anterior edge of the abutted lateral walls. Circular closure involves equal contributions from velum and lateral pharyngeal walls, while circular closure with Passavant's ridge also includes forward movement of the posterior pharyngeal wall resulting in a true sphincteric closure pattern (Figure 18.10).

Figure 18.10 Patterns of velopharyngeal valving. Source: Croft *et al.*, 1981.⁵⁴

Although nasoendoscopy is principally utilized as an investigative tool for elucidation of the underlying aetiology of and treatment selection for VPD, some have implemented videonasopharyngoscopy as an instrument for visual biofeedback of the velopharyngeal sphincter during speech.⁵⁵ Compensatory articulations may result in aberrant pharyngeal movements and the latter method has been effectively used to alter velopharyngeal movements or valving pattern prior to surgery, improving prognosis for success. Others contend that correction of misarticulations with speech therapy alone can improve pharyngeal wall motion without the need for visual biofeedback. In general, nasoendoscopy cannot be performed in uncooperative children or those younger than age 4 years.

In contrast, multiview *videofluoroscopy*, with or without barium coating, also widely implemented to assess the above-mentioned parameters, can often be performed in children below 4 years of age. In the authors practice, *lateral view* videofluoroscopy only is performed, as this view is deemed to provide the most anatomic and diagnostic information with regards to *levator* function, and its functional relation to the posterior pharyngeal wall.⁵⁶ Effective velar length refers to the portion of the soft palate that contributes to velopharyngeal closure, located between the posterior edge of the hard palate and *levator knee* or eminence (Figure 18.11). The remaining portion of the velum extends below the contact region and therefore does not participate in closure. On lateral view videofluoroscopy, the effective velar length (*levator knee*), velar excursion and the level of attempted palatal contact (velopharyngeal closure) can be ascertained. Moreover, posterior pharyngeal wall and Passavant's ridge displacement and direction of projection, as well as abnormal speech behaviours such as timing abnormalities and

Figure 18.11 Analysis of velar function. Measurements are made with the velum at rest in the nasal breathing position and at the point of maximum closure during production of the sound /i/. Levator function is best assessed during production of the sound /i/. A denotes the posterior edge of hard palate. Point B on the velum forms the *levator knee*. C, velar knee at the point of maximum closure. The levator knee is the bend in the soft palate formed by levator contraction. D, projection of line BC onto the posterior pharyngeal wall, in the line of the levator action, to identify the point on the posterior pharyngeal wall at which closure/contact would occur. AB, velar length at rest; AC, velar length at maximum closure or the functional length of the velum (extended length); AC/AB, extensibility; BD, velopharyngeal gap size at rest; CD, velopharyngeal gap at maximum closure; BC, velar excursion, distance travelled by the velar knee from the resting position to the point of maximum closure; BC/BD, closure ratio (1 = complete closure).

'tongue-backing' (where lingual movement is used to passively elevate the palate) can be seen during speech production.

Both nasoendoscopy and videofluoroscopy also allow visualization of tonsillar and adenoid tissue, which may impede palatal excursion or present a limitation to appropriate placement of pharyngeal flaps, respectively. Of note, in the presence of a palatal fistula, velopharyngeal function should be assessed with the fistula covered, as velopharyngeal movements have been shown to improve or even normalize once an associated fistula is occluded.⁵⁷ A limitation of videofluoroscopy is difficulty distinguishing right and left palatal excursion. However, a 'double levator knee' is usually apparent with asymmetric palatal movement.

A more objective measure of nasal resonance can be obtained with *nasometry*, where two separate measures of sound output from the nasal and oral passages are recorded during speech. A ratio of sound pressure energy generates a nasalance score. A high nasal score reflects a high degree of nasal emission, which is useful in cases where nasal air escape is inaudible in speech evaluation.

Static MRI may offer useful information regarding the position of the palate muscles. Dynamic real-time MRI scanning is a very promising future investigative tool, with the potential of providing three-dimensional visualization of the velopharyngeal port.

Upper airway assessment, including presence or absence of mouth breathing, snoring, obstructive sleep apnoea or nasal airway obstruction, is essential prior to surgical management of VPI. Further, a Mueller test may be performed, in which lateral pharyngeal wall stability on deep inspiration against obstruction (with mouth and nose closed) is also examined. In the presence of symptomatology suggestive of obstructive sleep

apnoea on preoperative evaluation, a polysomnogram is requested. If indicated (i.e. structural impediment to flap harvest and/or inset), tonsillectomy and/or adenoidectomy is performed 3–6 months prior to surgery.

Surgical management of velopharyngeal dysfunction

One of the primary principles of treatment for VPD is that *speech therapy will not correct VPI*. Following restoration of the structural elements to allow for velopharyngeal closure and correct nasal resonance, speech therapy is likely to be required to eliminate compensatory misarticulations and behavioural abnormalities (e.g. nasal grimace), as well as provide auditory reinforcement to promote closure. However, speech therapy can be applied if VPI is *intermittent* and therefore, although inconsistent, sphincteric closure can be achieved. Management of VPD aims to achieve satisfactory nasal resonance without inducing airway or nasal obstruction. Surgical management can be divided into palatal procedures and pharyngeal surgery.

Modifications to the velum include Furlow palatoplasty or palate re-repair with intravelar veloplasty. The former is implemented to lengthen the palate and re-establish the levator sling. Additionally, by performing a Z-plasty, recruitment of lateral pharyngeal tissue also results in tightening of the superior pharyngeal constrictor and consequently the velopharyngeal port.⁵⁸ The premise for palate re-repair with intravelar veloplasty is to retro-position the palatal musculature in order to recruit the residual soft palate for velopharyngeal closure, thereby optimizing the position and function of the levator (i.e. increasing effective velar length).⁵⁹ Moreover, buccinator flaps can be interposed at the junction of hard and soft palates in a short velum with adequate motility and posteriorly positioned levator musculature in an effort to achieve palatal lengthening.⁶⁰ Pharyngeal procedures include pharyngeal flap, pharyngoplasty and pharyngeal wall augmentation with either autologous or allogenic material. Figure 18.12 outlines the senior author's algorithm for the surgical management of VPI.

Figure 18.12 Algorithm for the surgical management of velopharyngeal insufficiency.

Pharyngeal flap

In 1865, Passavant described the original procedure for management of VPI in which adhesion between the soft palate and posterior pharyngeal wall was carried out, the forerunner of the pharyngeal flap.⁶¹ Later in 1875, Schoenborn introduced the inferiorly based pharyngeal flap,⁶² which he later modified to a superiorly based flap.⁶³ Rosenthal⁶⁴ reported on the use of a pharyngeal flap in primary cleft palate repair, where a pharyngeal flap was combined with a von Langenbeck palatoplasty. The posterior pharyngeal flap was popularized by Padgett⁶⁵ as a salvage procedure in patients with failed primary cleft palate repair. The pharyngeal flap is designed to create a passive central obturator in the velopharyngeal sphincter, leaving two lateral ports (Figure 18.13). Lateral gutters facilitate nasal breathing, nasal resonance and mucous drainage. Hogan⁶⁶ later refined pharyngeal flap design with the introduction of the concept of lateral port control, in which the size of the lateral ports are carefully calibrated at the time of surgery with the use of catheters placed through the two ports. In 1979, Shprintzen *et al.*⁶⁷ further advanced pharyngeal flap surgery with the advent of 'tailor-made' pharyngeal flaps, wherein the width of the flap is determined by the degree of lateral wall motion as seen on preoperative nasendoscopy and/or videofluoroscopy. Successful management of VPI with a pharyngeal flap necessitates satisfactory mesial movement of the lateral pharyngeal walls for lateral port occlusion,⁶⁸ and is therefore considered in patients with a sagittal closure pattern. If lateral wall motion is insufficient for lateral port closure (e.g. coronal closure pattern) or if the flap is too narrow (poor flap design) or attenuated (postoperative tubular contracture secondary to unlined flap under-surface), hypernasality may persist. In contrast, lateral port occlusion may result in airway compromise, hyponasality and mouth breathing.

Interestingly, Karling *et al.*⁶⁹ noted a correlation between flap width and adduction of the lateral pharyngeal walls. More specifically, patients with limited preoperative adduction demonstrated a greater increase in lateral wall excursion with a narrow flap than with a wide flap, whereas those with greater preoperative excursion showed a decrease in postoperative adduction in relation to flap width.⁷⁰ The latter 'learning phenomenon' provides one possible explanation for those patients that retain a certain degree of velopharyngeal competence following surgical flap division or dehiscence. Other potential reasons for persistent velopharyngeal function following flap resection include augmentation of the posterior pharyngeal wall with the residual flap remaining as a pad or possibly anatomic changes in the pharynx secondary to the initial surgery, such as narrowing of the velopharyngeal port due to scar contracture at the donor site.

The most common complications of pharyngeal flap surgery include bleeding and airway compromise. The most notable complication is the potential for obstructive sleep apnoea. There are a number of other factors that contribute to obstructive sleep apnoea following pharyngeal flap harvest, in addition to the mechanical barrier of the flap per se at the level of the

Figure 18.13 Diagrammatic illustration of key steps in the operative technique for superiorly based pharyngeal flap harvest and inset. (a) The superiorly based flap is incised in the posterior pharyngeal wall and the soft palate is divided in the midline. (b) Posteriorly based flaps of nasal lining of the velum are elevated. (c) The pharyngeal flap is inset onto the nasal surface of the soft palate and the previously raised flaps from the nasal surface of the palate are used to line the raw (oral) surface of the pharyngeal flap. (d) The soft palate is closed in the midline, along with the donor defect in the posterior pharyngeal wall.

nasopharynx. Moreover, syndrome-specific features may aggravate any mechanical obstruction. More specifically, obstruction is often secondary to lateral wall collapse against a wide pharyngeal flap. The latter is especially notable in patients with VCFS, in whom generalized muscular hypotonia presents a predisposition for pharyngeal wall collapse and obstruction. In addition, obstruction may occur as a result of flap harvest, which also narrows the lower portions of the pharynx, thus increasing resistance in the oro- and hypopharynx. The latter is secondary to the flap donor site that remains to heal by secondary intention thereby creating circular contraction.

Other factors include posteriorly displaced tonsils that extend within the lateral ports and occlude the nasopharyngeal airway. Tonsillar hypertrophy may also compromise the oropharyngeal airway, as circular contraction brings them in closer proximity. Obstructive sleep apnoea occasionally necessitates division of the flap, when not amenable to non-surgical management.

Caution should be exercised when selecting pharyngeal flap surgery in patients with VCFS, in view of the high prevalence of medial displacement of the internal carotid arteries. This poses significant risks in execution of this procedure given that the abnormal positioning of the vasculature in the pharynx is coincident with the region of pharyngeal flap harvest. Moreover, the danger of ectopic localization of the arteries is aggravated by the characteristically thin pharyngeal musculature. Many favour evaluation of the cervical vasculature with MRI angiography prior to consideration of surgical velopharyngeal correction. However, the results obtained with more sophisticated imaging modalities cannot be extrapolated to the patient at the time of operation, where the internal carotids adopt a less median position with neck hyperextension. Thus, routine vascular imaging, even when aberrant pulsations are noted on preoperative nasoendoscopy, does not appear crucial or reliable. According to Mehendale and Sommerlad,⁷¹ the most reliable measure is direct

observation and palpation of the pharynx at the time of surgery. If necessary, the position and width of the pharyngeal flap can be modified to minimize the risk of artery exposure.

Pharyngoplasty

Hynes⁷² described a technique for pharyngoplasty, where bilateral superiorly based musculomucosal flaps were elevated from the lateral pharyngeal walls and inset onto the posterior pharyngeal wall. Flaps included salpingopharyngeus and were later modified to contain the descending fibres of the palatopharyngeus and a portion of the superior constrictor.^{73,74} The elevated flaps, based at the level of the Eustachian cushions, are transposed 90° and sutured to the posterior pharyngeal wall, which is incised transversely from the superior end of the posterior limb of one lateral flap to the other, at the level of attempted velopharyngeal closure or atlas (first cervical vertebra) (Figure 18.14). The flaps are inset in overlapping fashion.^{73,74} In his original description, Hynes described division of the soft palate in order to gain access to the nasopharynx and facilitate flap inset. Pharyngoplasty

attenuates VPD by diminishing the central velopharyngeal space. This procedure is used in patients with a coronal or circular closure pattern and adequate palatal motion, or hypotonic velopharynx. In effect, these flaps are used to *augment the posterior pharyngeal wall*, thereby reducing the palatal movement necessary to achieve closure.

Orticochea^{75,76} described a pharyngoplasty that is quite distinct from the Hynes pharyngoplasty, despite the two procedures being often confused. In this operation, the flaps are raised from the posterior tonsillar pillars, based superiorly and containing palatopharyngeus muscle. The flaps are transposed and inset into a short but wide inferiorly based posterior pharyngeal flap *below* the level of attempted closure in the oropharynx and below that of the Hynes pharyngoplasty as previously described (Figure 18.15). Jackson and Silverton⁷⁷ modified this procedure by altering the inferiorly based flap to a superiorly based flap in an effort to bring the flaps closer to the level of attempted closure, but later eliminated the supplementary posterior pharyngeal flap. Orticochea proposed the notion of *dynamic*

Figure 18.14 Diagrammatic illustration of the key steps in the operative technique for modified Hynes pharyngoplasty. (a) Bilateral palatopharyngeus muscle flaps are outlined. (b) The muscle flaps are elevated and transposed. (c) Flaps are sutured together end-to-end, as well as to the posterior pharyngeal wall.

(a) Bilateral flaps from the posterior tonsillar pillars and an inferiorly based flap on the posterior pharyngeal wall are outlined. (b) The flaps are elevated and transposed. (c) The flaps are inset into the posterior pharyngeal flap.

pharyngoplasty, claiming that the transposed flaps of palatopharyngeus maintain intrinsic contractile function and therefore produce an active sphincter that assists in velopharyngeal closure (hence the term ‘sphincter pharyngoplasty’). However, many would argue that the dynamic nature of this procedure is questionable. Moreover, despite initial optimism that it would produce less airway compromise than a posterior pharyngeal flap, evidence suggests it is equally obstructive.

Prosthetic management

Non-surgical management is indicated in patients with a completely hypodynamic velopharyngeal mechanism (e.g. neuromuscular disorder), in those for whom surgical intervention is contraindicated or those with severe or persistent airway obstruction that is recalcitrant or not amenable to conservative management. Non-operative treatment consists of placement of a prosthetic device, either palatal lift and/or pharyngeal obtu-

rator. The palatal lift device is used to reposition the palate to a location where minimal excursion is required to effect closure, while the pharyngeal obturator acts to occlude the defect in the velopharyngeal sphincter.

Management of unilateral or asymmetric velopharyngeal insufficiency

Management of unilateral or asymmetric VPI includes pharyngeal bulb, skewed pharyngeal flap, unilateral pharyngoplasty and unilateral adhesion of the adynamic hemi-velum to the posterior pharyngeal wall. Mehendele and Sommerlad⁷⁸ described the use of a *unilateral* Moore pharyngoplasty flap to support the non-functioning or poorly functioning side of the velum, thereby assisting the active contralateral levator to elevate the entire velum. As originally described, the Moore pharyngoplasty involves bilateral postero-lateral pharyngeal flaps that are inset into a transverse incision at the junction of the middle and

posterior thirds of the nasal surface of the velum.⁷⁹ Goals of this procedure include obliteration of the lateral pharyngeal recesses, increase tissue bulk on the nasal surface of the velum at the point of potential contact of the velum with the posterior pharyngeal wall, and possibly velar lengthening. Moreover, the flaps are thought to augment the action of the levator by forming an active muscular sling. As previously mentioned, unilateral or asymmetric VPI is a common finding in patients with oculo-auriculo-vertebral spectrum.^{80,81}

CHAPTER 19

Congenital ear anomalies

Sabrina Cugno¹ and Neil W. Bulstrode²

¹Department of Plastic and Reconstructive Surgery, Montreal Children's Hospital, Montreal, Quebec, Canada

²Department of Plastic Surgery, Great Ormond Street Hospital for Children, London, UK

Ear development

The intricate contours of the external ear are attributed to delicate elastic cartilage covered with a thin layer of subcutaneous tissue and skin. The ear develops around the first branchial cleft, which is the groove between the first (mandibular) and second (hyoid) arches. Auricular development begins during the fifth week of gestation. At the sixth week of embryogenesis six tubercles appear on the first and second branchial arches, the *auricular hillocks of His*. The three anterior hillocks of the mandibular arch give rise to the tragus, root of the helix and superior helix, respectively, and the three posterior hillocks of the hyoid arch form the remaining components of the auricle (Figure 19.1). The development of the ear is usually complete by the fourth month of gestation.¹ The auricles are initially positioned on the embryonic neck, and progressively migrate from this antero-caudal location postero-cranially as the mandible enlarges until they reach their final anatomic location by week 20. As a result, remnants of the developing ear may be found at any point along this route, often localized to the pre-auricular region, so-called *pre-auricular skin tags*. Rarely polyotia may be encountered, considered an extreme form of the rudimentary skin tag, distinguished by both size and morphology. Polyotia bears resemblance to the normal external ear and is often termed *mirror ear*, with a conjoined conchal bowl in place of the tragus (Figure 19.2). The middle ear structures are also derived from the first and second branchial arches, and external auditory meatus and canal from the first branchial groove. Thus, patients with microtia typically have atresia of the external auditory canal and tympanic membrane, as well as variable deformities of the middle ear ossicles. Before subtleties of congenital anomalies can be recognized, the topography of normal ear must be appreciated (illustrated in Figure 19.3).

Although the ear has its definitive form at birth, the auricular cartilage of the neonatal ear retains distinct malleability due to enduring high levels of circulating maternal oestrogen. Oestrogen upregulates the production of hyaluronic acid, which increases the pliability of cartilage. Oestrogen levels are highest

in the first 3 days after birth and decrease to a level comparable to older children at six weeks of age.² During this privileged period, *deformational* anomalies of the auricle can be corrected by non-operative means with external moulding devices. Authors have reported excellent results when correction is initiated within 3 days of birth.^{2–4} Thereafter, adjustment of deformational irregularities, such as auricular *malformations*, must be effected by surgical means. There is no consensus as to the upper age limit at which splinting therapy can be considered, nor reliable evidence on the length of time needed for auricular moulding.

There is marked variability in the phenotypic expression of congenital deformities of the ear, challenging classification of these anomalies. Marx⁵ published the first classification system, followed by Tanzer in 1978⁶ (Table 19.1). Congenital auricular anomalies can be categorized as either malformations or deformations. The malformed ear presents hypoplasia of cartilaginous and cutaneous constituents and gross morphological aberrations, whereas the deformed auricle has a normal chondrocutaneous component but irregular architecture. Further, although malformational anomalies arise from a combination of genetic and environmental factors, deformational abnormalities are deemed to result from external forces applied to the developing or neonatal ear and/or abnormal morphology or function of the three extrinsic and/or six intrinsic auricular muscles. The intrinsic musculature is mainly vestigial at birth but during auricular morphogenesis has an integral role in folding of the ear.

At birth, the normal auricle is approximately 66% of its adult size. The superior aspect of the helix is at the level of the tail of the eyebrow and the inferior aspect of the lobule corresponds to the base of the columella, with the long axis of the auricle inclined posteriorly at approximately 20° from vertical. At 5 years of age, the ear has grown to within 8 mm of its full adult vertical height (approx. 5.5–7 cm), and is therefore approximately 87% complete. Ear length reaches its mature size at age 13 in males and age 12 in females. In contrast, ear width at age 5 years has attained approximately 97% of its adult size.

Table 19.1 Comparison of the ear deformity classification systems of Marx and Tanzer

Marx ⁵	Tanzer ⁶
Grade I. Abnormal auricle with all identifiable landmarks	Type 1. Anotia
Grade II. Abnormal auricle without some identifiable landmarks	Type 2. Completely hypoplastic ear (microtia) a. With atresia of the external auditory canal b. Without atresia of the external auditory canal
Grade III. Very small auricular tag or anotia	Type 3. Hypoplasia of the middle third of the auricle Type 4. Hypoplasia of the superior third of the auricle a. Constricted (cup or lop) ear b. Cryptotia c. Hypoplasia of entire superior third Type 5. Prominent ear

The width of the ear continues to grow until age 7 and 6 in males and in females, respectively (width is approx. 55% of the length, 3–4.5 cm).⁷ Age at external ear maturity has important implications regarding timing of operative correction.

Prominauris

Ideal projection of the normal external ear is often cited as 1.5–2 cm from the scalp, and the projection of the helix from the mastoid as 10–12 mm in the superior portion, 16–18 mm and 20–22 mm in the middle and inferior portions, respectively.⁸ The auricle is considered as prominent if on frontal view it projects beyond these limits.

Prominent ears or prominauris is the most common congenital abnormality of the ear. It is associated with an autosomal dominant inheritance pattern with variable penetrance. This deformational anomaly is qualified by one or a combination of the following features:

- effacement or reduced definition of the antihelical fold;
- prominence of the concha (overdevelopment of the posterior wall of the concha and/or increased angle between mastoid and concha); and
- prominence of the lobule.

Other commonly associated features include excessive angulation of the helical root from the temple, absence of the helical roll (*shell ear* deformity) and macrotia. There is no consensus regarding the optimal age at which to perform correction (otoplasty), and surgery may be considered as early as age 4 years. Ideally, the authors' preference is to delay correction until at least age 6 years. At this age the ear has nearly attained its final

adult size and, although anecdotal, the increased rigidity of the auricle at age 6 appears to decrease the occurrence of inadvertent damage to the cartilage, which can result in irregularities in auricular form.

Numerous techniques have been described for correction of each of the three above-mentioned features of the prominent ear. With regards to re-creation of the antihelical fold, cartilage manipulation can be classified as cartilage suturing, cartilage scoring and cartilage breaking. Cartilage breaking involves placing a full-thickness cartilage incision or excision along the curve of the antihelix and superior crus, which permits the cartilage on either side of the incision to fold into position. As an alternative to this technique, initially proposed by Luckett in 1910,⁹ surgeons made a pair of incisions parallel to the desired antihelical fold and placed sutures between the two.¹⁰ The latter technique was modified by Converse *et al.*¹¹ and later Converse and Wood-Smith¹² to obviate the sharp fold of the antihelix that often results. Mustardé is credited for creation of the antihelical fold with suture fixation, wherein at least three full-thickness mattress sutures are placed to span the antihelix, with each suture purchase including cartilage and both perichondrial layers (Figure 19.4).¹³ Interestingly, Luckett in his original paper⁹ suggested that the antihelical fold could be created by appropriate suture placement, although he did not explore the concept.

Cartilage scoring techniques, as popularized by Stenström¹⁴ and Chongchet,¹⁵ are based on the principle of Gibson and Davis¹⁶ that cartilage tends to warp away from the abraded perichondrial surface. Some authorities contend that so-called conchal excess is in fact secondary to a lack of antihelical fold, and once the fold is restored any apparent 'excess' will be corrected. In

fact, Mustardé and Stenström address conchal protuberance by rolling back the posterior conchal wall, such that it is integrated into antihelix formation. Alternatively, conchal hypertrophy can be corrected with excision of a crescent-shaped cartilage segment (with or without overlying skin), through either an anterior or posterior approach, with care taken to avoid violation of the antihelix. Conchal-mastoid sutures, originally described by Owens and Delgado¹⁷ and later modified by Furnas,¹⁸ may be added to effect desired conchal setback, where the concha is sutured to the mastoid fascia and/or periosteum (Figure 19.5). Suture placement effectively rotates the concha forward and outward, thereby increasing the protrusion of the angular ledge that marks the junction of the concha with the external auditory canal. Thus, when this procedure is carried out one must be cautious to avoid narrowing of the external auditory meatus. Spira and Stal¹⁹ devised a laterally based conchal cartilage flap to appose to the mastoid periosteum, which decreased the tendency to obstruct the external auditory canal.

On the basis of cadaveric studies, Goulian and Conway²⁰ described the cartilage of the helix and concha as two discrete components, separated by a distinct fissure, and advocated relocation of the cauda helices (helical tail) onto the cavum conchae to reposition the prominent lobule. The latter is based on the commonly advanced premise that lobular protrusion is due to a displaced cauda helices.²¹ Many surgeons have subsequently adopted this approach and developed various technical modifications to retro-position the helical tail. Various other methods to address lobule prominence have been illustrated, such as fishtail excision of skin on the posterior surface of the lobule, wedge resection of the skin on the medial aspect of the lobule, and suture fixation of the lobule to the mastoid fascia.

Figure 19.4 Diagrammatic illustration of Mustardé mattress suture placement for creation of an antihelical fold. (a) Posterior view of ear showing mattress sutures inserted from posterior aspect of cartilage at predetermined marks. (b) Coronal section with mattress suture inserted, to show 'bite' of cartilage and perichondrium. (c) With suture tightened to produce optimum folding. Source: Mustardé, 1963.¹³ Reproduced with permission of Elsevier.

Figure 19.5 Diagrammatic illustration of key steps in the operative technique for placement of conchal-mastoid sutures as originally described by Furnas. Source: Furnas, 1968.¹⁸ Reproduced with permission of Lippincott, Williams & Wilkins.

There are a number of complications associated with otoplasty, which differ depending on the technique used. With cartilage suturing, suture extrusion and granuloma formation may occur, necessitating suture removal and resulting in recurrence of ear prominence. Cartilage irregularities and/or deformity are more likely to occur with cartilage scoring and/or breaking techniques. Haematoma and infection are two early complications that can occur with any technique and merit more detailed mention. With regards to haematoma formation, rapid recognition and appropriate management is essential. In the early postoperative period, onset of severe, often unilateral pain should prompt the immediate removal of the head dressing and if haematoma is confirmed, sutures released to drain the collection. Infection is another

potentially devastating complication of prominauris correction, which mandates aggressive management with intravenous antibiotics, as chondritis and cartilage deformity may ensue if not effectively controlled. Either of the latter two complications can result in significant cartilage destruction, for which correction may involve formal ear reconstruction with rib cartilage.

The authors' preferred method for prominauris correction is therefore a modified Mustardé technique for antihelix formation with or without Furnas' method for conchal setback.²² In the majority of cases, otoplasty is performed under general anaesthesia. The procedure begins with design of a conservative dumb-bell-shaped outline for skin excision on the posterior (medial) side of the auricle. Following infiltration of local anaesthesia to

the posterior auricular surface in the subcutaneous plane, skin excision is performed and the posterior auricular skin is dissected off the perichondrium. If placement of Furnas sutures is anticipated, dissection is extended to the ponticulus (conchal ridge, site of posterior auricularis muscle insertion) and an area of mastoid fascia for suture placement is exposed. Many often use a needle charged with methylene blue to mark the points for recreation of the antihelix. The needle is passed from the anterior (lateral) side and thus tattoos the exposed posterior cartilaginous surface at the desired location for suture placement. The authors do not utilize the latter technique, relying instead on familiarity with the architecture of the cartilage as viewed from the medial surface to identify the conchal border, triangular fossa and scapha, as underscored by Rubin *et al.*²³

The authors prefer to use a non-absorbable braided suture for cartilage fixation. Following antihelical fold formation, conchal prominence is assessed. If deemed excessive, Furnas sutures are placed with no conchal cartilage excision, in an effort to reduce the distance between concha and mastoid. In his original technical description, Furnas divided the posterior auricularis muscle fibres and posterior auricular ligament, which extend from the ponticulus to the mastoid fascia, prior to suture placement.¹⁸ Given that sutures are placed anterior to the muscle insertion on the concha and that great auricular nerve fibres span this area, the authors prefer to not divide these structures, ensuring rather that the posterior auricularis muscle is not strangulated with suture positioning. The latter is thought to avert the postoperative pain that may ensue following placement of conchal-mastoid sutures. If the lobule requires retro-positioning, dissection is extended into the lobe such that a deep suture is placed from both the tail of the helix and the subcutaneous lobular tissue to the floor of the concha. The latter is an effective means to address lower third prominence and avoids tissue excision in and scar on the earlobe. Once haemostasis is assured, the incision is closed with a running horizontal mattress with absorbable suture and a head dressing is applied for 2–5 days. Once the dressing is removed, the patient is instructed to wear a headband for six weeks.

Other auricular anomalies

Although prominauris typically presents bilaterally, other auricular deformities are usually unilateral. For unilateral correction, irrespective of the auricular anomaly, a template of the *normal* ear is made and the size or deformed part on the ear requiring correction is then addressed based on its contralateral counterpart.

In *Stahl's ear* deformity, a third crus projects from the antihelix toward the helical rim at an approximate right angle, flattening the helix and widening the scapha. Aberrant insertion of the intrinsic transverse muscle has been postulated as the aetiological origin of this anomaly.²⁴ For correction of Stahl's ear various techniques have been described, including wedge

excision of the auricular segment occupied by the third crus, excision of the abnormal cartilage with reshaping to approximate the scaphal concavity, and removal of the anomalous cartilage section and substitution in a reversed position.

Cryptotia is a congenital auricular anomaly seldom seen in the white populations, but is common among East Asian populations, with a reported incidence of approximately 1 in 400 among the Japanese. It occurs when the superior pole of the auricle is buried beneath the scalp skin, resulting in a lack of superior auriculocephalic sulcus, as well as associated distorted cartilage architecture.^{25,26} It has been suggested that the invagination of the upper portion of the auricle is attributable to aberrant insertion of the superior auricularis muscle into the upper portion of the helix. Normally this extrinsic muscle extends from the epicranial aponeurosis to the dorsal protuberance of the triangular fossa.²⁷ The deformity of the cartilage results from anomalous intrinsic auricular musculature, namely, intrinsic transverse and oblique muscles, which mould the auricle into its characteristic shape.²⁸ The transverse muscle, which extends from the conchal eminence to the scapha, forms the body of the antihelix and superior crus. The oblique muscle, between the eminence of the concha and triangular fossa, shapes the inferior crus. Although numerous techniques have been described for correction of this abnormality, the underlying principles of reconstruction are similar. That is, cartilage plasty depending on the degree of cartilaginous deformity, and local tissue rearrangement to fill the gap created in the superior portion of the retro-auricular sulcus and posterior aspect of the ear once the superior pole of the ear has been distracted from the scalp and fibrous soft tissue adhesions released. Methods to address the cutaneous defect include Z-plasty, V-Y plasty, advancement flap, a combination of local flap and skin graft or tissue expansion.

In 1970, Cosman *et al.* described a congenital ear anomaly where the ear resembles a question mark secondary to prominence of the upper third of the auricle, deficiency or absence of scapha and helix in the middle third, and partial or complete disjunction of the lobule.²⁹ So-called *question mark ears* are a defining feature of the *auriculo-condylar syndrome*, an autosomal dominant disorder first described by Uuspää in 1978; it is further characterized by mandibular condylar agenesis or hypoplasia and other mandibular anomalies.³⁰ Cosman *et al.*²⁹ proposed correction with cartilage excision along the antihelix–superior crus (thereby reducing auricular height and width) and Z-plasty closure with interdigitation of split helical rim and lobular flaps (for correction of the cleft above the lobule), similar to procedures used for auricular reduction in cases of macrotia. Although satisfactory results were achieved, the authors prefer formal reconstruction with costal cartilage based on principles advanced by Firmin for secondary reconstruction following otoplasty complications.³¹ Firmin states that any deformity involving more than one quarter of the ear, more than two anatomical planes or complex contours necessitates correction with costal cartilage. The skin is addressed with a double type

2 transfixion incision effected at the level of the auricular cleft, in which the superior and inferior portions of the ear are individually transposed and the intermediate mastoid skin recruited for framework coverage.

The terms *constricted*, *cup* and *lop ear* are often used interchangeably to describe variants of a similar auricular anomaly. Tanzer proposed a classification for constricted ears, which is valuable for reconstructive management of this deformity.³² Group 1 involves the *helix only*, where the superior portion of the helix is folded, giving what Cosman referred to as a lidded appearance³³ and Rogers called a *lop ear*.³⁴ The latter can often be addressed with simple excision of the excess skin and cartilage, as auricular height is usually adequate. Alternatively, for cases with a characteristically angulated superior helical rim, the involved portion of rim can be detached and repositioned. The deformed segment of cartilage can be dissected from the scapha and transposed to the posterior surface of the scapha as either a pedicled flap or free graft. In group 2a, the *helix and scapha* are involved, lidding is more significant with increased constriction of the helical rim. Further, features of the prominent ear may be present, including ill-defined superior crus and

enlarged conchal cavity. However, the cutaneous envelope is adequate, such that correction of the malformed cartilaginous structure can be re-draped with the existing skin. The latter often qualifies the *classic lop ear*.

The authors' preferred method of correction for this group is the technique described by Musgrave,³⁵ who elaborated on the procedure first described by Stephenson³⁶ (Figure 19.6). This approach involves complete de-gloving of the superior pole cartilage. Thereafter, radial full-thickness incisions are made in the lidded segment of cartilage, which allows the cartilage to unfurl in a postero-superior direction, thereby restoring auricular height and width. Scoring of the anterior surface of the cartilage can be effected to assist with transposition of the multiple segments created. A conchal cartilage graft is harvested from either the contralateral or ipsilateral (as originally described by Musgrave) ear and used as a curved strut to maintain the cartilaginous segments in place and bridge the gaps in the expanded helical rim. The cutaneous envelope is re-draped over the refashioned cartilage framework and the reconstruction supported with bolsters placed in the scapha beneath the helical rim and on the posterior surface of the ear. If necessary,

Figure 19.6 Diagrammatic illustration of key steps in the operative technique for lop ear correction described by Musgrave. Source: Musgrave, 1966.³⁵ Reproduced with permission of Lippincott, Williams & Wilkins.

a posterior skin approach can be added to address auricular prominence. Namely, placement of Mustardé sutures for re-creation of the antihelical fold.

The primary distinguishing feature between groups 2a and 2b is *skin deficiency* in the latter subgroup. In this case, the constriction is more significant and the malformed ear has characteristics of both lop and prominent ears, including an overdeveloped concha, deficient superior helical margin, antihelical crura and antihelical body and diminished auricular height (to which the term *cup ear* is usually applied). Indeed, Cosman described the constricted ear deformity with four major features: lidding, protrusion, decreased ear size and auricular dystopia; and advised cartilage expansion and supplemental skin coverage for a size discrepancy of 1.5–2 cm when compared to the normal contralateral ear, which is consistent with a Tanzer type 2b ear. Group 3 is not unlike a conchal-type microtia deformity. As groups 2b and 3 involve deficiency of both skin cover and underlying cartilage, reconstruction necessitates framework fabrication with costal cartilage and recruitment of regional skin, as described in the following section for microtia reconstruction.

Microtia

The pathogenesis of *microtia* remains elusive, with phenotypic expression ranging from pre-auricular skin tags to *anotia* (or complete absence of the auricle). Microtia is a developmental malformation of the external ear with an estimated prevalence between 0.83 and 17.4 per 10 000 births.³⁷ The incidence of microtia differs among ethnic groups, being greatest among Asians (especially Japanese). Microtia occurs 20–40% more commonly in males, involves the right side in nearly 60% of unilateral cases and bilateral deformity accounts for approximately 10% of cases.³⁸ The genetic and cellular mechanisms responsible for the normal morphogenesis of the external ear remain incompletely defined. Microtia appears to be associated with single gene mutations in syndromic and familial cases, whereas in sporadic cases a combination of genetic and environmental factors or polygenic causes are involved. The genetic contribution to microtia is supported by the higher concordance in monozygotic versus dizygotic twins, familial cases with autosomal dominant and recessive modes of inheritance, as well as the more than 18 microtia-associated syndromes for which chromosomal aberrations or single gene defects have been elucidated.

Current theories for microtia development include high altitude, neural crest cell disturbance and vascular disruption.³⁸ Evidence in support of the role of neural crest cells is derived from recent studies on the causative mechanisms of various teratogens on microtia, including retinoids and diabetic embryopathy. The development of microtia following localized vascular insult during embryogenesis is primarily supported by studies of Poswillo,^{39,40} in which unilateral ear and mandibular anomalies resulted following

ipsilateral haematomas at the junction of pharyngeal and hyoid arteries when monkeys were exposed to thalidomide and mice to triazine. This long-standing theory has been challenged by evidence of bilaterality in isolated microtia, as well as the occurrence of non-craniofacial anomalies frequently seen in oculo-auriculo-vertebral spectrum. Johnston and Bronsky⁴¹ disputed Poswillo's original experiments and contended that the development of haematomas was delayed in relation to drug exposure and that significant branchial arch hypoplasia preceded haemorrhage.

Although more commonly an isolated unilateral abnormality, in some patients microtia portends other, perhaps more subtle, craniofacial anomalies. Accordingly, a number of cases present as a component of more complex craniofacial disorders. Most notable are those associated with aberration of first and second branchial arch derivatives, namely the *oculo-auriculo-vertebral spectrum*. Microtia may also constitute an important diagnostic feature of various other craniofacial syndromes, including Treacher Collins, Nager, Townes–Brocks, Kabuki, CHARGE, Meier–Gorlin, branchio-oto-renal and branchio-otic syndromes. Indeed, approximately 20–60% of patients with microtia have other anomalies or an identifiable syndrome.³⁸ Noteworthy associated abnormalities include renal anomalies, cardiac defects, oral clefts, microphthalmia, polydactyly and vertebral irregularities. In view of the latter, clinical assessment of these patients must include observation for these commonly associated features.

Patients with microtia should be treated by a specialist multidisciplinary team including plastic and reconstructive surgeon, otolaryngologist and audiologist. Initial assessment should include a formal audiologic evaluation, with either auditory brainstem response testing in the newborn or audiogram in the child, which are mandatory to determine the degree and type of hearing loss. Microtia with aural atresia is associated with conductive hearing loss, although a small minority may exhibit sensorineural hearing loss despite the discrete embryonic origin of the internal ear. In the presence of an atretic external auditory canal, middle ear deformity and presence of cholesteatoma must be assessed. More advanced radiologic examination may be indicated for elucidation of anomalous temporal bone (middle ear/ossicles) and facial nerve anatomy, which provides anatomic detail essential for any projected otologic surgery. More recent evidence has shown that with regards to academic and career attainment patients with unilateral hearing loss benefit from auditory rehabilitation with an amplification device, as functionally these patients have difficulty with localization of sound and understanding in noisy environments.⁴² Patients with bilateral microtia and conductive hearing loss require early fitting with a bone-conduction hearing device to avert impairment of speech development. The current gold standard for hearing rehabilitation is an osseointegrated bone-anchored hearing aid (BAHA).⁴³ Ideally, this device should be placed 65–70 mm posterior to the external auditory meatus or site of future placement of the ear construct. The authors do not currently advocate surgical restoration of the external auditory conduit (canaloplasty) and middle ear due to the associated

postoperative morbidity, including infection, desquamation, meatal restenosis and inconsistent results in hearing improvement. If canaloplasty is considered, it should follow external ear surgery, as any resulting scarring of the area impedes subsequent reconstruction. In general, at the time of the second stage of auricular reconstruction (sulcus formation), a neo-auditory canal is drilled and covered with local fascial flap and skin graft or directly with skin graft.⁴⁴ However, surgical results are generally poor and as such the latter practice is not universally recommended in patients with bilateral microtia and certainly not in those with unilateral microtia. In a recent report on international trends in the treatment of microtia, authors noted that the great majority of centres did not perform middle ear reconstitution.⁴⁵

Reconstruction

Although Gillies⁴⁶ is credited as the first to propose the use of autogenous costal cartilage for auricular framework fabrication, the modern era of ear reconstruction began in 1959, when Tanzer reintroduced the use of rib cartilage for autologous microtia reconstruction, which is still recognized as the gold standard reconstructive option.^{47,48} Following the original precepts of Tanzer, Brent^{49,50} refined autogenous reconstruction with the introduction of his four-stage technique. The primary advance contributed by Brent was placement of the cartilaginous framework in ideal position *prior* to transposition of the lobule,

which is the reverse of Tanzer's sequence. When the lobular remnant is transposed at the first stage, placement of the ear construct must be adapted to the lobe with a compromise on location. In 1993, Nagata published his modified two-stage approach to autologous microtia reconstruction, wherein the lobule is transposed in the *same* stage as framework fabrication (including the tragus) and placement.^{51–55} Thus, Nagata's first stage combines the first, second and final stage of Brent's technique. In addition, both authors proposed their own respective classification systems to describe the variable appearance of the microtia deformity. A detailed comparison of the latter two classifications and techniques is provided in Table 19.2.^{49–56}

In the authors' practice, auricular reconstruction is realized as a two-stage procedure, as initially described by Nagata and later modified by Firmin.^{57–59} Autologous reconstruction is offered at the minimum age of 9 years, depending on the physical and psychological maturity of the child. At this age, there is usually sufficient costal cartilage for framework fabrication and most children have the requisite level of understanding to be an active member in the treatment plan and postoperative rehabilitation and care. For the first stage of reconstruction, following induction of general anaesthesia, preoperative markings are made. On the unaffected side, two distances are outlined and transposed onto the side with microtia: the distance between the lateral canthus to the most anterior point of the helix and between the lateral commissure to the lowest point of the lobule. The latter two measures determine the anterior- and inferior-most points for placement of the reconstructed ear.

Table 19.2 Comparison of two classifications and techniques for microtia reconstruction

	Brent ^{49,50,56}	Nagata ^{51–55}
Microtia classification		
Types	1. Classical microtia (sausage-shaped vestige, usually with absent external auditory meatus) 2. Atypical microtia (concha, antihelix, tragus, antitragus, with absence of upper portion of ear, with or without presence of external auditory canal)	1. Lobular microtia (ear remnant with malpositioned lobule, without concha, external auditory meatus and tragus) 2. Conchal microtia (lobule, concha, with or without external auditory meatus, tragus, antitragus with incisura tragica, present to variable degrees) 2a. Small type, or 2b. Large type (depending on degree of conchal development)
Operative technique		
Number of stages	3 (stage 2 and 3 combined) or 4 1. Cartilage framework fabrication/placement 2. Transposition of lobule 3. Elevation of ear construct and creation of auriculocephalic sulcus 4. Tragus construction, conchal excavation and contralateral otoplasty, if indicated	2 1. Cartilage framework fabrication (with tragal component)/placement and transposition of lobule (Brent stage 1, 2 and 4) 2. Elevation of ear construct and creation of auriculocephalic sulcus
Age at reconstruction	4–6 years	10 years (or chest circumference at xiphoid, 60 cm)
Skin incision	Small incision anterior to vestige	W-shaped skin incision
Costal cartilage	Contralateral ribs, 6–8	Ipsilateral ribs, 6–9
Framework fixation	Clear nylon sutures	Wire sutures
Dressing	Closed suction drains	Bolsters
Tragus construction	Chondrocutaneous graft from contralateral ear	Rib cartilage
Elevation of ear construct and creation of auriculocephalic sulcus	Occipitalis turnover flap and skin graft with cartilage wedge	Temporoparietal or posterior auricular fascial flap and skin graft with cartilage wedge

Next, the angle between the axis of the nasal dorsum and the normal ear is ascertained and this angle is marked on the abnormal side and used to determine the inclination of the ear construct. Finally, the course of the superficial temporal artery is marked using a Doppler probe. An outline of the normal ear is drawn onto X-ray film, which serves as the template for fabrication of the auricular framework. Once the location of the future ear on the abnormal side is determined, the outline of the normal ear is drawn, potential adaptations of the microtic vestige are assessed and then the appropriate skin approach is selected (Figure 19.7).

The costal cartilage segments of ipsilateral ribs 6–8 are harvested through a 5 cm oblique incision along the costal margin, preserving the posterior perichondrium *in situ*. The cartilaginous base block is fashioned from the synchondrosis of ribs 6 and 7 with cartilage sculpting effected on the surface denuded of perichondrium (as the perichondrial surface ensures cohesion of the cartilaginous block to the recipient bed). Thus, the posterior surface of the harvested cartilage becomes the anterior surface of the reconstructed ear. The helix and antihelix are shaped from the eighth rib. The tragus, antitragus, tragal bar and cartilage block for framework elevation (second stage) are carved from remaining cartilaginous segments, and fixed in place with 38-gauge wires (Figure 19.8). During the carving of the auricular framework, cartilage shavings and unusable cartilaginous fragments are collected, morcelized and placed in a Vicryl mesh sleeve that is then used to reconstitute the costal margin.⁶⁰ Intercostal nerve blocks (chirocaine, 2.5 mg/mL) are carried out for postoperative analgesia prior to inset of the mesh, and the cartilage block for the second stage is banked in a subcutaneous pocket along the inferior margin of the chest incision.

Based on the morphology of the microtia, Firmin⁵⁸ proposed a classification system, perhaps more useful than those of her contemporaries, based on the type of skin incision required for framework placement. Originally, type 1 skin incision was used for typical lobular microtia and involved lobular transposition

with Z-plasty. However, Firmin has now abandoned type 1 skin incision in favour of type 2, transfixion, skin incision. This technical adaptation came from observation of tenuous vascularity of the posterior skin flap. The transfixion incision is indicated for both lobular and conchal-type microtia, where the inferior portion of the auricle is sufficiently developed to accept the lower extremity of the framework. The latter approach consists of a full-thickness transverse incision of the remnant auricle, thereby creating two skin edges. The posterior skin edge is sutured to the inferior skin edge of a corresponding transverse incision in the mastoid skin, and the anterior skin edge is sutured to the edge of the superiorly based skin flap that covers the cartilage framework. Type 3 skin incision is subclassified into type 3a, which is used when the ear is malformed but comparable in size to the contralateral side, such that the deformed cartilage can be dissected from the skin envelope and the framework placed into the cutaneous pocket (sulcus is preserved, single stage reconstruction), and type 3b, which is implemented for cases of anotia or where the microtic remnant cannot be used (e.g. significant auricular dystopia).

Once the appropriate skin incision is made and the amorphous remnant cartilage is removed, the auricular pocket is dissected in the plane deep to the subdermal vascular plexus, with dissection extended beyond the limits of intended framework placement (marked auricular outline) to recruit sufficient skin to adequately cover the contours of the construct without undue tension. The cartilage framework is placed in the subcutaneous pocket over two suction drains. If a temporoparietal fascial flap is required for partial or complete coverage of the cartilaginous framework (e.g. low temporal hairline or inadequate skin envelope in, for instance, cases of secondary reconstruction), it is harvested following dissection of a subcutaneous pocket through a 4 cm chevron-type incision placed at the apex of the temporal fossa, centred over the superficial temporal artery. The fascial flap is then covered with a split-thickness skin graft harvested from the contralateral scalp.

Figure 19.7 Preoperative measurements and markings for assessment of ideal location for the reconstructed ear, as outlined in the text. (a) Estimation of the ideal location. (b) During surgery, landmarks are used to correctly place the reconstructed ear.

Figure 19.8 Framework fabrication. (a) A 5 cm oblique incision is marked along the costal margin ipsilateral to the side to be reconstructed. (b) The cartilage segments of ribs 6–8 are harvested and the framework fashioned as described (c, d). More recently, the authors have modified framework fabrication and no longer sculpt the tragus and antitragus segments as a single unit. Instead, the antihelix and antitragus are shaped as a single component and a cartilaginous strut is made to span the base block, on which the tragus is placed (e). (f) Intraoperative result at the end of the first stage of reconstruction.

Since January 2007, reconstruction for cases of bilateral microtia has been executed simultaneously, with each step of this operative sequence performed in tandem. No dressings are applied to the reconstructed ear(s) to enable constant surveillance of the skin envelope and underlying construct. Patients are admitted to hospital for 4 nights, where the ear(s) is monitored and the vacutainer drains are changed every 4 h to maintain the skin maximally applied to the contours of the framework. Patients are placed on a 24-h course of intravenous antibiotics, followed by oral antibiotics for a total of one week. On day 7, the drains are removed and the patient is discharged from hospital.

The second stage is routinely performed six months later, with the exception of first-stage reconstruction necessitating temporoparietal fascial flap coverage of the construct, for which an interval of 12 months must elapse before framework elevation and sulcus formation. The framework is released through a peri-helical incision extending to fascia. Elevation of the ear construct is buttressed by placement of the previously banked cartilage block behind the antihelix (positioned to form the posterior conchal wall). Although a temporoparietal fascial flap is commonly used for coverage of the framework and cartilage block, the authors prefer a random pattern galeal fascial flap. The retro-auricular skin is advanced toward the sulcus and the

posterior surface of the ear, auriculocephalic sulcus and mastoid region are surfaced with a split-thickness skin graft harvested from the ipsilateral scalp (Figure 19.9). Following the second stage, patients are admitted overnight to complete a 24-h course of intravenous antibiotics, and then discharged on oral antibiotics for 7 days. The dressing remains in place until the first postoperative visit at one week. At two weeks, the auriculocephalic sulcus is fitted with an elastomer ear splint.

The second stage presents an opportunity to carry out other refinements to the ear construct and/or additional reconstructive procedures to enhance facial form and/or symmetry. This combined reconstructive approach has become the authors' routine practice, with complementary procedures including contralateral prominauris correction, ear piercing, fat transfer for soft tissue augmentation, as well genioplasty and malar augmentation to camouflage any associated bony deficiency.⁶¹ Typical results achieved following completion of two-stage microtia reconstruction are shown in Figure 19.10.

Although modifications and refinements in technique have been developed over the last several decades, the optimal management of

several aspects of autologous microtia reconstruction remain unresolved and debated by current leaders in the field of autologous ear reconstruction. Some authorities contend that the second stage of reconstruction should be reconsidered as creation of the auriculocephalic sulcus can result in a loss of framework definition. Further, optimal management of significant bony deficit, as is common in cases of severe craniofacial microsomia, remains in dispute.

Oculo-auriculo-vertebral spectrum

As previously mentioned, microtia is an integral component of a number of syndromes, including the *oculo-auriculo-vertebral spectrum* (more commonly referred to as hemifacial or craniofacial microsomia). In effect, it is now well established that microtia is a *forme fruste* of the craniofacial malformation sequence associated with hemifacial microsomia.⁶¹ However, all structures derived from the first and second branchial arches may be affected, unilaterally or bilaterally to different degrees.

Figure 19.9 Second stage of reconstruction. Early postoperative result achieved following completion of two-stage reconstruction in a patient with unilateral isolated microtia.

Figure 19.10 Result achieved following completion of two-stage reconstruction in a patient with bilateral isolated microtia, on whom each stage of reconstruction was performed simultaneously for both sides.

Moreover, other extracranial malformations may be present, including vertebral, renal and limb anomalies. In these patients, significant dystopia of the vestige secondary to underlying deficiency of the craniofacial skeleton, notably the temporal bone, as well as soft tissue hypoplasia, renders selection of appropriate location for construct placement difficult. In addition, the external auditory meatus and canal may be in an ectopic position necessitating transposition.⁶³ Thus, achieving a symmetric result presents a particular reconstructive challenge, especially when auricular reconstruction is one of several elements in the reconstructive sequence for facial dysmorphism (Figure 19.11). Moreover, craniofacial deficiency is often associated with an insufficient skin envelope for framework coverage, as well as a low temporal hair-line resulting in hair extending onto the skin that will drape the superior portion of the ear construct. Tissue expansion has been suggested to address the former and temporoparietal flap fascial

harvest for framework cover is generally used to deal with the latter. Although more detailed description of reconstructive modifications in the presence of these features is beyond the scope of this chapter, these general points are mentioned for completeness.

Complications

There are a number of complications associated with autologous auricular reconstruction, related to both donor site and the site of reconstruction. With regards to donor site, the most notable complication is chest wall depression, often cited by proponents of synthetic reconstruction as a primary argument against costal cartilage harvest for framework fabrication. Leaving the posterior perichondrium *in situ* may potentially lessen chest wall

Figure 19.11 Patient with severe manifestation of the oculo-auriculo-vertebral spectrum who presented with significant dystopia of the auricular remnant.

morbidity by promoting cartilage regeneration at the donor site. In our practice, we have found that reconstitution of the costal margin, as previously described, minimizes potential contour deformity. During rib harvest, one may inadvertently create a breach in the parietal pleura, resulting in pneumothorax. This is typically identified during the procedure and the pleural defect promptly repaired.

At the level of the reconstructed ear, the most common complication is exposure of the cartilage framework, which may occur as a result of extrusion of suture/wire material or vascular compromise of the overlying skin envelope. The latter mandates early recognition and appropriate treatment as cartilage resorption and distortion of the final form of the ear construct may result. In general, areas of exposure $>10 \text{ mm}^2$ require surgical management with debridement and cutaneous or fascial flap coverage, depending on the location relative to the contours of auricle and adjacent tissue mobility (Figure 19.12).

Smaller defects can usually be addressed conservatively with local wound care. The most significant complication is infection with consequent cartilage resorption. Infection, usually

secondary to *Pseudomonas*, most often occurs in the presence of a vestigial external auditory canal. Infection may also ensue following construct exposure. Additional complications include haematoma or seroma formation, cartilage framework resorption or fracture.

Alternative reconstructive options

The poor results achieved with autogenous cartilage in early reconstructive efforts encouraged others to find alternative options for framework fabrication. Popularized by Cronin *et al.*^{64,65} and refined by Ohmori *et al.*,^{66,67} Silastic was used as a preferred implant material for auricular reconstruction for over two decades. High rates of implant extrusion necessitating explantation, however, limited its continued use and costal cartilage, accredited largely to Tanzer, became the preferred framework material.

Although autogenous reconstruction is now considered the primary reconstructive option in the paediatric population, two other alternative options should be mentioned, which also preclude

(a)

(b)

Figure 19.12 (a) Patient with oculo-auriculo-vertebral spectrum who presented with right unilateral lobular microtia. Twenty-nine days following the first stage of reconstruction, she presented with total necrosis of skin overlying the concha. (b) Coverage of the area of exposed cartilage graft was restored with harvest of a random superficial mastoid fascial flap, which was tunnelled beneath the cartilaginous ear construct to reach the distal extent of the defect. The fascial flap was then grafted with a split-thickness skin graft, harvested from the scalp (skin graft donor site shown).

harvest of costal cartilage for auricular framework construction, namely, composite autogenous/alloplastic reconstruction and prosthetic reconstruction. The former consists of framework fabrication with porous polyethylene (Medpor) and coverage of the framework with a temporoparietal fascial flap, as popularized by Reinisch and Lewin.⁶⁸ The porous structure of this material has proved a major advantage over smooth silicone implants, providing improved adherence to surrounding tissues. Further, fascial flap coverage has decreased the rates of implant extrusion, providing more robust soft tissue support.

Prosthetic reconstruction in children is considered a salvage option following failed secondary autologous reconstruction where costal cartilage or soft tissue coverage remains insufficient for consideration of additional autogenous or alloplastic reconstruction. The latter option involves retention of the silicone auricular prosthesis with osseo-integrated titanium implants.

Finally, further advances in stem cell and tissue engineering to obtain a cartilaginous scaffold, may, in future, obviate the need for costal cartilage harvest and prove the ideal solution for framework fabrication.⁶⁹

CHAPTER 20

Craniofacial clefts

Irene M.J. Mathijssen and Sarah L. Versnel

Department of Plastic, Reconstructive Surgery, and Hand Surgery, Erasmus MC, University Medical Center Rotterdam, Rotterdam, The Netherlands

Craniofacial clefts encompass a wide range of deformities that is not easily delimited. Only seldom is a true clefting of both the soft tissue and underlying bone involved. One can therefore debate whether or not all diagnoses that are included in this chapter actually should be classified as a craniofacial cleft. Shedding more light on their pathogenesis will undoubtedly change the way we classify these conditions in the future. The occurrence rate of rare facial clefts is estimated to range from 1.43 to 4.85 per 100 000 births. In South America, Africa and Asia, the incidence of rare facial clefts appears to be higher than in Europe, the United States and Canada.

Aetiology

For an increasing number of craniofacial disorders, the genetic background is recognized (Table 20.1). For true midline clefts, it is more likely that a genetic factor is involved, and a crucial role appears to be played by the cranial neural crest cells during embryogenesis. Frontonasal dysplasia and hypertelorism appear to be mediated through excessive Hedgehog activity, which causes enhanced neural crest cell proliferation in the facial prominences.¹⁴ In Treacher Collins syndrome, on the other hand, haploinsufficiency of the protein *Tcof1* is shown to result in increased cell death of neural crest cells.¹⁵ For a significant number of disorders the pathogenesis is still unknown.

Classification

Multiple proposals have been made to create order in the broad spectrum of facial clefts. Tessier's topographic classification is the most frequently used anatomical classification.¹⁶ It differentiates 15 locations for clefts with the palpebral fissure as central landmark; cleft axes 0 (30) to 7 below the fissure represent the facial clefts, and clefts 8–14 above the fissure are referred to as the cranial clefts (Figure 20.1). The system includes a description

of the course of each cleft through both soft tissue and bone, which are rarely affected to the same extent.

Various other proposed classifications take the pathomorphogenesis of clefts into account; of these, van der Meulen's embryological classification is the most comprehensive. In this system the term 'dysplasia' is used since not all malformations are true 'clefts'. The dysplasias are classified according to time and location of developmental arrest.¹⁷

Hypoplasia of the mandible is graded according to the Pruzansky classification¹⁸ and as adapted by Mulliken and Kaban¹⁹ (Table 20.2).

Diagnostics

With the recent progress in three-dimensional ultrasonography and the discovery of pathogenic genes, prenatal diagnostics have gained importance.²⁰ Early recognition of the condition can optimize perinatal care (anticipation of airway problems), timely referral, and parents can be more specifically advised on expectations, treatment and outcome by an experienced team.

For a solid treatment plan, a three-dimensional computerized tomography scan is required for essential information on the condition and position of the osseous structures. An MRI is performed to evaluate intracranial structures, especially in median and paramedian clefts, and in case of suspicion of encephaloceles.

Management principles

General considerations

Surgical treatment of facial clefts is a major reconstructive challenge that is often underestimated. Frequently soft and hard tissues of multiple areas of the face are affected in various degrees of severity. This results in three-dimensional deformities with both aesthetic and functional impairment. In the majority of patients multiple cleft types exist and asymmetry

can be present. The goal of surgery is to achieve a good functional and aesthetic outcome.

Although these challenging facial deformities are appealing to many surgeons, patients with a facial cleft should be referred to a specialized centre. Even initial small corrections can result in extensive scarring, patchwork or insufficient reconstructions. Moreover, initial excellent results may deteriorate gradually over time due to intrinsic impaired growth or growth disturbance by surgical interventions; in addition mild deformities at birth can become more obvious over the years.^{17,21,22} Therefore, a long-term individual treatment plan by an experienced team is required to optimize end-results at adulthood and limit the number of operations.

Besides growth, the timing of surgery is also influenced by functional problems such as breathing, insufficient protection of the eye and feeding difficulties that require early intervention. Psychological aspects also play a role. ‘School-going age’ and teasing are often seen as a reason for early substantial reconstructions. However, research has shown that the intensity of the psychological burden is not directly related to the objective severity of the deformity.²³

Because of the rarity and enormous variability of facial clefts, it is impossible to establish standardized methods of treatment. However, certain general treatment principles apply as a foundation for each individual treatment plan.^{21,22,24–26}

- manage functional problems early;
- minimize scars and plan them within the borders of the facial units;
- avoid short-term solutions, and take the influence of growth into account;
- establish a good skeletal base for soft tissue coverage;
- attempt to restore the muscle layer by transposition and fixation of dystopic remnants;
- restore mucosal and conjunctival lining;
- use stable fixation to the skeleton for the cutaneous layer in order to optimize and preserve facial contour;
- preferably use techniques for skin coverage that can be reused (e.g. cheek advancement).

Airway management

Acute treatment of a patient with a (cranio)facial cleft is required whenever breathing is obstructed. In most cases, the breathing is normal while the child is awake, but gets obstructed when the child is asleep and the tongue is repositioned and the pharyngeal wall musculature relaxes. During sleep, repeated episodes of reduced (hypopnoea) or blocked breathing (apnoea) may occur, referred to as obstructive sleep apnoea (OSA). A polysomnography is the gold standard to obtain data on presence and severity of obstructive breathing. An upper airway endoscopy is advised in case of OSA to check for all possible sites of airway obstruction, ranging from septum deviation, choanal atresia, nasopharyngeal obstruction, obstruction at the tongue base level or cricoid stenosis.

Mild OSA can often be overcome by placing the baby in prone position. In some types of malformations there is a natural tendency to overcome the OSA, such as in Pierre Robin sequence, whereas in other types such as Treacher Collins syndrome this does not occur. Follow-up with repeated polysomnographies is therefore required for all patients to determine their individual breathing pattern over time and to adjust treatment as required. For newborn patients with severe OSA, a tracheotomy should be considered, as distraction at this very young age can be difficult given the cartilaginous aspect of the mandible. Securing the airway with a cannula allows time for the patient to age, which makes both the anaesthesia and surgery more predictable and safe. Distraction of the mandible in (very) young children has a higher risk of failure, will cause damage to teeth buds and will hamper future surgery which is very likely required. Most surgeons therefore tend to postpone distraction of the mandible until after the first year of age, and will only perform it if a decannulation seems feasible.

Special attention should be given to the palate, which may have a (submucous) cleft. If a cleft is present in a patient with other features of a (cranio)facial cleft, one should not apply the usual protocol regarding timing of palate closure. The chances

of inducing an upper airway obstruction is much higher and may require postponing closure of the palate until growth of the facial skeleton allows unhampered breathing. To determine safety of palatal closure, one can perform an overnight polysomnography with the patient wearing a custom-made palatal plate that mimics the closed palate. If this measurement shows no significant airway obstruction, repair of the cleft palate can usually be undertaken although one has to take into account that some swelling postoperative may temporarily cause additional obstruction. Close postoperative monitoring of the breathing pattern is thus required. Whenever severe OSA is present, one should be aware of the likelihood of associated swallowing and feeding difficulties.

Mandible

A true cleft of the mandible (type 30) is very rare and generally combined with a midline cleft of the lower lip and adherence of the tongue to the floor of the mouth.²⁷

In most cases of a craniofacial cleft with mandibular involvement, the mandible is hypoplastic on one or both sites. If breathing is not at risk, a mandibular distraction can be indicated to correct the occlusion and the facial asymmetry. There is no consensus at which age this should be undertaken and individual factors should be weighed. These factors are, for instance, the degree of asymmetry, problems with chewing, dental status and psychosocial considerations.

Maxilla

Midface hypoplasia is frequently encountered in craniofacial clefts. Depending on the type of cleft the hypoplasia may also be unilateral, causing severe facial asymmetry, particularly in the oblique facial clefts.²¹ If the degree of hypoplasia is significant, advancement with distraction may be indicated. For each patient an individual planning is made on whether a Le Fort I, II, III or a combination of, for instance, Le Fort I with advancement of the zygoma is required.

The orbits

Several abnormal positions of the orbits can be encountered in craniofacial clefts, particularly orbital dystopia and hypertelorism. Orbital dystopia refers to a difference in the vertical position of the orbits, with one of the orbits positioned higher or lower compared to the contralateral orbit. Oblique maxillary clefts often involve a bony defect of the orbital floor, combined with an intrinsic growth restriction in all directions of the maxilla. In unilateral cases, this impaired growth adds to the degree of orbital dystopia over time. Repair of the orbital floor with the insertion of a bone graft is usually undertaken at a young age, and may be combined with bone grafting of the maxillary cleft.²⁶ This grafting of the floor results in a partial correction of the dystopia. Definitive correction of orbital dystopia through a box osteotomy is usually delayed until the age of 6 years, as the osteotomies at the maxillary level are more likely to damage the tooth buds at a younger age.

Figure 20.2 Facial bipartition to reduce interorbital distance and widen the alveolar arch.

In hypertelorism, the distance between both orbits is increased due to true lateralization of the orbits, which is commonly encountered in midline facial clefts. It should be distinguished from interorbital hypertelorism (or pseudohypertelorism) in which only the distance between the medial canthi is enlarged. Correction of hypertelorism can be undertaken with an orbital box osteotomy, or with a facial bipartition.²⁸ This last procedure simultaneously corrects the high-arched palate and V-shaped maxilla (Figure 20.2), resulting in a stable outcome in the long term.^{21,22} Following a facial bipartition, temporal depression is often encountered and this can in most instances be corrected with lipofilling. Timing of hypertelorism correction is controversial regarding the occurrence of relapse if performed before the age of 6. Several authors reported no relapse of hypertelorism,^{21,29} but initial undercorrection was a frequent finding. Others state that initial severe hypertelorism and correction under the age of 6 increases the chance of relapse.³⁰

In case of a severe microphthalmia or anophthalmia, early placement of serial orbital conformers should be considered to expand the orbital volume, followed by the insertion of a definite ocular prosthesis with or without a fat–dermis graft.

The eyelids

Semi-acute treatment concerns the protection of the eyes in case of an exposed cornea, which is particularly the case in patients with a large coloboma of the eyelid(s). A coloboma is a localized part of the eyelid characterized by hypoplasia of skin, muscle, tarsal plate, conjunctiva and eyelashes. Initially, the cornea may be protected with the use of lubricating gels and protective eye-wear, but within a few weeks an eyelid reconstruction is indicated. Local flaps for correction of colobomas give good initial results. However, only a minority remain stable over time, resulting in ectropion in the long term. A cheek flap provides good results, replaces like with like and can be reused when

necessary; this in contrast to other local flaps such as, for example, the forehead flap.²¹ Good positioning of the medial canthal tendon is necessary since it often displaces laterally and inferiorly.

The nasolacrimal system is often involved, with partial or complete deficiency in clefts involving the medial orbit. Dacryocystorhinostomia is performed at a later stage. Frequently secondary canthal and eye corner corrections are required.

The nose

A wide variety in presentation of nasal anomalies exist in facial clefts. Specific for midline clefts is the bifid nose. This deformity may be as mild as only a bifid tip of the nose, but may also involve a nose duplication, or even a true separation of both nasal halves in combination with hypertelorism, an encephalocele and absence of all midline structures. If the deformation is that severe, a facial bipartition is indicated which would also correct the widened nasal bridge with the removal of a significant amount of bone at the level of the glabella and the nasal bones. At the same time, a rib graft can be inserted to augment the nasal dorsum and columella as they often have insufficient support. Reduction of the nasal tip can also be done with limited dissection to remove the excess of soft tissue in between the medial crurae and suture the cartilage together to define the nasal tip.

Several options are available to correct the flattened nose, including using autologous material, particularly cartilage and bone, or using alloplastic material, such as silicone. Advantages of using autologous material include the reduced rate of infection, while a disadvantage is the donor site morbidity and resorption of the graft that might occur. Donor sites for autologous grafts are usually the ribs, the calvarium or the iliac crest. Whether or not cartilage should be used for the reconstruction remains unclear and is mostly determined by preference of the surgeon. In a comparative study between bone grafts no obvious

advantage for either graft type was detected regarding outcome or complication rate.³¹

In general, reconstruction is delayed until midfacial growth is nearly complete.³² In clefts with abundant tissue over the nasal dorsum, rearrangement of the skin should be considered with the use of an L-incision.³³ If the midline skin is severely dysplastic, direct excision of the affected tissue and a midline scar cannot be avoided.²⁶ Extensive correction of the nasal deformity, including the use of a forehead flap, should be postponed to adult age, and combined with correction of the nasal septum if so indicated. Prior to this surgery, one has to be certain that the maxilla is in the right position and if this is not the case, the advancement of the maxilla should precede any nasal reconstruction, as it influences tip projection.

In paramedian and oblique clefts a range of alar deformities (true clefting, hypoplasia, upward displacement, broadening, flattening) can be present, but also hemi- or total aplasia of the nose with or without a proboscis (rudimentary tubular 'nasal appendage'); the shape of piriform aperture can be altered or absent. Some use a proboscis for initial (hemi)nasal reconstruction. Since this proboscis consists of dysplastic soft tissue which lacks normal growth, it should be excised; otherwise it only contributes to unnecessary scarring.

Small alar defects can initially be managed with local flaps when sufficient soft tissue is present. Often they require secondary corrections for asymmetry or result in too much scarring.^{21,34}

Encephaloceles and craniosynostosis

In some types of craniofacial clefts, encephaloceles and/or craniosynostosis may be part of the malformation. The encephalocele is usually repaired within the first year of life with the use of a cranial bone graft to close the vault defect. Preoperative evaluation with MRI of the ventricular size and cerebrospinal fluid (CSF) collection at the site of the encephalocele is required and the insertion of a ventriculoperitoneal shunt may be indicated, as the persistent pressure of a CSF collection on a bone graft may cause its resorption.

The cheek

An oblique cleft through the cheek (type 3) is considered the most difficult to repair.¹⁶ Due to shortage of skin, a cheek rotation flap is indicated; it gives much better results than local closure and Z-plasties.^{21,26,35,36} Tissue expanders can be used in large defects and secondary reconstructions to achieve aesthetic subunit reconstruction. An attempt of reconstruction of the muscle layer should always be made,^{35,36} as is the case for macrostomia.³⁷

Associated syndromes

Frontonasal dysplasia

The group of frontonasal dysplasia is rather heterogeneous one. It includes the diagnoses of EFN1-mediated craniofrontonasal syndrome, constituting a distinct phenotype.¹ Discovery of the

ALX3 mutations separated another group of patients within the midline cleft, referred to as frontorhiny.² These patients are characterized by hypertelorism, wide nasal bridge, short nasal ridge, bifid nasal tip, broad columella, widely separated slit-like nares, long philtrum with prominent bilateral swellings, and midline notch in the upper lip and alveolus. ALX4 mutations were discovered in patients with a similar but very mild phenotype.⁴ In 2013, Uz showed mutations in ALX1 to result in an extreme presentation with bilateral microphthalmia, bilateral oblique facial clefts, complete cleft palate next to hypertelorism, wide nasal bridge and hypoplasia of the ala nasi.³

Another separate group within the frontonasal dysplasia cohort are patients with a basal encephalocele, who present with hypertelorism, a bifid nose tip, an incomplete midline cleft of the upper lip and a cleft palate with an encephalocele hanging down in the mouth through the skull base defect.²²

Treacher Collins syndrome

The syndrome is characterized by hypoplasia of the zygomatic arches, mandibular hypoplasia, beaked nose, lower eyelid colobomas or partial absence of eyelashes, downslanting of the palpebral fissures, dental anomalies, various degrees of microtia and atresia of the external auditory canal with anomalies of the middle ear ossicles, speech abnormalities, with or without a cleft palate.³⁸ The facial features present in a symmetric way. Treacher Collins syndrome is caused by mutations in the *TCOF1*, *POLR1D* and *POLR1C* genes and the inheritance pattern is autosomal dominant (Table 20.1).

Patients with Treacher Collins syndrome are highly likely to have OSA^{39,40} and should all be screened with a polysomnography.⁴¹ In a series of 50 patients, 4 required an immediate tracheostomy.⁴² If a cleft palate is part of the phenotype (in 23% in the paper by Thompson *et al.*⁴²), special attention to the breathing pattern should be given prior to closing the palate. Hardly any normal growth of the mandible takes place, prior to or following mandibular distraction.⁴³ There are several options to correct the bony deficiency of the malar complex. Most surgeons prefer autologous bone over implants, especially in children and particularly given the poor soft tissue coverage. Most commonly, cranial bone is used to augment the orbitozygomatic complex and this can be either taken as a pedicled graft on the superficial temporal artery⁴⁴ or as a free graft.⁴⁵ In the series reported by Thompson *et al.*,⁴² no difference in survival of the bone graft was seen between the pedicled and the free grafts. The characteristic nasal deformity may be corrected at an adult age, after completing maxillary advancement if indicated.

Reconstruction of the lower eyelid coloboma and the low position of the lateral canthus is performed with a laterally based flap of the upper eyelid. Jackson⁴⁶ suggested taking a full-thickness flap from the upper eyelid, including tarsus and conjunctiva, while completely releasing the retraction of the lower eyelid. In milder cases, a musculocutaneous flap lined with a mucosal graft is usually sufficient to augment the lower eyelid skin. Fullness to the lower eyelid and upper part of the cheek can be provided through lipofilling.

Most patients with Treacher Collins have a significant hearing deficit based on hypoplastic middle ear cavities and ankylotic or missing ossicles.⁴⁷ Therefore, a bone-anchored hearing aid (BAHA) is often required. The planning of external ear reconstruction and placement of a BAHA should be coordinated so as to not compromise outcome of the two interventions.

Nager syndrome

The typical craniofacial features of Nager syndrome are severe micrognathia, malar hypoplasia, eyelid anomalies such as coloboma and downward slanting, mild anomalies of the external ear, and a low hairline. These anomalies present in a symmetric way. A cleft palate can be present. Functionally, hearing⁴⁸ and breathing are commonly impaired and often a tracheotomy is required. Characteristically, hand anomalies such as hypoplasia of radius and ulna, radioulnar synostosis, thumb aplasia and clinodactyly are present and make the distinction from Treacher Collins syndrome.

The severe hypoplasia of the mandible does not improve in time and thus surgical correction is indicated to improve breathing. Several papers report successful mandibular distraction, allowing the removal of tracheotomies in some patients, but usually not in all.⁴⁹ If a class I occlusion is achieved, an additional genioplasty distraction with hyoid advancement may further improve sleep studies and appearance.⁵⁰

Oculo-auriculo-vertebral spectrum, or hemifacial microsomia

The phenotype of hemifacial microsomia (HFM) is very wide, ranging from a preauricular skin tag and minor asymmetry of the mandible to the full-blown presentation with orbital dystopia, severe asymmetry of the mandible and absence of the temporomandibular joint, soft tissue deficiency, facial nerve palsy, microtia, hearing loss, cleft lip/palate and macrostomia. The various features of HFM are graded in the OMENS classification (orbit, mandible, ear, cranial nerves and soft tissues) with 0 for normal to 3 for severely affected.⁵¹ Facial nerve dysfunction was reported to occur in 22% of HFM patients,⁵² while 10% have an associated cleft lip/palate and 23% macrostomia.⁵³ The malformation has an incidence of 1 in 5000 and usually occurs unilateral but may be present bilaterally in approximately 10–15% of patients. Other frequently encountered congenital malformations are skeletal, cardiac, central nervous system, gastrointestinal, renal, and pulmonary disorders,⁵⁴ or dental anomalies.⁵⁵

The spectrum of oculo-auriculo-vertebral anomalies also includes the Goldenhar syndrome, the phenotype of which is identical to that of hemifacial microsomia in combination with anomalies of the cervical spine and an epibulbar dermoid. The dermoids are usually only removed whenever they interfere with visual acuity.⁵⁶

Children with HFM are more likely than otherwise healthy children to have symptoms of sleep-disturbed breathing.⁵⁷ Since the introduction of distraction of the mandible by McCarthy

et al.,⁵⁸ this is the primary choice of treatment for correcting the hypoplastic side of the mandible. Although adequate lengthening can be achieved, the width of the lower face often remains impaired. This deformity can either be corrected by using autologous bone grafts or with an implant. The discussion on optimal timing for mandibular distraction, however, continues. Early distraction has a higher rate of complication and may be associated with the necessity to repeat surgery at a late age. A critical review of literature clearly showed a lack of evidence to substantiate long-term effectiveness of early mandibular distraction.⁵⁹ To reduce the rate of repeat surgery, overcorrection until the chin points to the non-affected side is recommended. Only the very severely affected mandibles require reconstruction with a free flap,⁶⁰ or the insertion of a rib graft with secondary distraction of the graft or the native mandible.³⁰ Reconstruction of the temporomandibular joint in the class III deformity is a major challenge, with often disappointing results regarding mouth opening. In the severe types of malformations, usually a rib graft is inserted with a cartilaginous part facing the skull base and the interposition of soft tissue (temporalis fascia flap or buccal fat pad) to prevent ankylosis. Implants are in general not applicable in these severely affected patients.

After correcting the skeletal deformity, a significant soft tissue deficiency usually remains. The options for its correction are either serial procedures of lipofilling or a free flap. In a comparative study between both techniques in patients with comparable deformities, a mean number of two sessions for the free flap group (microsurgical revisions and secondary corrections) and four sessions of lipofilling were required.⁶¹ Downside of using a free flap is the donor site morbidity, difficulty in the acceptor site due to previous surgery, and the tendency of the flap to sag. In this group there was an overcorrection of the volume. In the lipografted patients there was a 83% fat take and an almost symmetrical result. Given the lower complication rate and good results, lipofilling is an excellent way to correct the soft tissue deficiency.

Binder

Patients present with the characteristic features of nasomaxillary hypoplasia with flattening of the nose. On examination, the cartilaginous septum is missing and there is hypoplasia of the nasal bones, the anterior nasal spine and pyriform apertures. These anomalies appear not to induce difficulties with breathing. In general, there is no shortage of soft tissue but extensive undermining is required to reduce the mechanical restraints on the graft.⁶²

Good results with various techniques using rib are presented by Chiang *et al.*⁶³ and similarly by Goh and Chen³² who not only restored the nasal dorsum with a strut for the columella, but also augmented the pyriform apertures.

Parry-Romberg syndrome or hemifacial atrophy

Parry-Romberg is characterized by a progressive disappearance of the subcutaneous fat in one half of the face, and may also involve the skin, muscle, cartilage and bone. Patients are more

likely to have neurological abnormalities, such as epilepsy.⁶⁴ Involvement of the skin can present as hyperpigmentation, depigmentation or alopecia of the scalp. The syndrome is often related with linear scleroderma en coup de sabre.⁶⁵ The process usually starts in the first or second decade of life and then stops after several years. Reconstruction is only undertaken when one is sure that there is no more progression of the disease. In the very severe cases, both bony and soft tissue reconstruction is performed, whereas in the mild cases only lipofilling in several sessions may be sufficient.⁶⁶

(Pierre) Robin sequence

There is a large discrepancy in diagnosis of (Pierre) Robin sequence, which makes interpretation and comparison of the numerous studies difficult.⁶⁷ The most generally accepted criteria for Pierre Robin sequence are mandibular hypoplasia, glossoptosis and breathing difficulties. In over 80% of the cases a cleft palate is present, which is generally U-shaped. The isolated Robin sequence is distinguished from the syndromic form, in which the triad is part of, for instance, Stickler syndrome, velocardiofacial syndrome or Treacher Collins syndrome.

To overcome the obstructed breathing, prone positioning is usually sufficient and within several months' time, sufficient mandibular growth resolves the problem. For the minority of patients in whom breathing is insufficient despite prone positioning, the options can be tongue–lip adhesion, nasopharyngeal airway, non-invasive respiratory support, tracheostomy and mandibular distraction. The tongue–lip adhesion has been presented as a successful procedure,⁶⁸ although not routinely advocated or used in several craniofacial centres. Treatment for several months with a nasopharyngeal airway solved the breathing problems in all patients in the London team, obviating any surgical procedure.⁶⁹ Non-invasive respiratory support has very similar results.⁷⁰

The long-term effectiveness of mandibular distraction in patients with Pierre Robin sequence is not proven, as is the case for this procedure in hemifacial microsomia. Numerous case reports are presented to demonstrate its good outcome, but it should be kept in mind that most patients do not require this procedure if given the time to allow for mandibular growth. Distraction should be reserved for those patients with a tracheostomy, an obstruction only at the tongue–base level, and adequate bone quality to allow placement of the distraction device.⁷¹ Decannulation can not always be achieved, however.⁷²

Stickler syndrome and Marshall syndrome

The phenotype in these syndromes consists of ocular (particularly myopia), orofacial (flat midface and cleft palate) and hearing anomalies. Hearing loss is particularly sensorineural and to some degree conductive.⁷³ Given the high risk of retinal detachment, close follow-up by an ophthalmologist is required.

Velocardiofacial, Shprintzen or 22q11.2 syndrome

The velocardiofacial (VCF) syndrome is most commonly encountered in patients with syndromic cleft palate. The facial characteristics encountered are overfolding of the helix and cup ears, prominence of the nasal radix, narrow alar base and bulbous nose tip, fullness of the upper eyelids, malar flattening, elongated lower face height, retrognathia and facial asymmetry.⁷⁴ The syndrome is also associated with developmental disabilities, intellectual disability and a high risk of psychiatric disorders.⁷⁵ Many patients have a mild to moderate immune deficiency, and the majority have a cardiac anomaly. Patients with VCF are likely to have medially displaced internal carotid arteries, which is a risk during pharyngeal flap dissection. In a comparative study, this anomaly was encountered in 44% of VCF patients and in 14% of controls.⁷⁶ The course of the cervical part of the internal coronal artery was irrelevant, however, to the design of the pharyngeal flap and thus preoperative magnetic resonance angiography (MRA) was no longer recommended.

CHAPTER 21

Craniosynostosis

Aina V.H. Greig¹ and David J. Dunaway²

¹Department of Plastic Surgery, St Thomas' Hospital, London, UK

²Department of Craniofacial Surgery, Great Ormond Street Hospital, London, UK

History

Hippocrates provided the first description of craniostenosis in 100 BC, noting the variation of skull deformities and correlating them with patterns of cranial suture involvement.^{1,2} There are many historical descriptions of people with unusual head shapes.^{1,2} The Greek statesman and general Pericles had an unusually long narrow head shape and was nicknamed 'Squill Head'. It is possible he had sagittal synostosis. In *The Iliad*, Homer described a man called Thersites whose head was pointed at the top. Aristophanes and Galen both used the term *oxycephalus* for 'tower head'.²

The term *craniosynostosis* was first used by Otto in 1830³ to describe the entity of premature suture fusion. Virchow described how in medieval Saxony, people believed that such children were thought to be changelings or monsters and that it was the devil who made them deaf, dumb and blind.^{4,5} Virchow examined skulls from various museums and published a classification in which he correlated synostosis of specific cranial sutures with head shape.^{2,4,5} What has become known as Virchow's law is that premature fusion of a cranial vault suture (craniosynostosis) inhibits skull growth perpendicular to the fused suture and compensatory overexpansion takes place at patent sutures.^{2,4,5}

The general direction of growth after synostosis is parallel to the fused suture. For example, when synostosis of the sagittal suture occurs, growth proceeds in an anteroposterior direction, leading to scaphocephaly and a long, narrow, boat-shaped skull (Figure 21.1).

Skeletal development

The developing skull is divided into the neurocranium, which surrounds the brain, and the viscerocranium, which develops into the facial bones. The neurocranium is made up of bones that ossify directly, the membranous neurocranium which forms the skull vault, and bones that undergo endochondral

ossification and form the skull base.⁶ The flat bones of the skull grow by the deposition of new bone material at their margins. In their growth phase, these bones do not fuse but remain separated by specialized structures, the cranial sutures. Skull growth is needed to accommodate the size of the growing brain and depends on an exchange of signals between mesenchyme, the osteogenic front and the dura mater (for review, see Slater *et al.*⁷ and Striker and Mundlos⁸).

Normal calvarial growth

Normal growth of the calvarium is complete at about age 2 years, the orbit at age 6 years, and the rest of the facial skeleton at about age 16–17 years. Brain growth drives the enlargement of the skull in infancy. The expanding brain doubles in size in the first six months of life and then doubles again in the second six months and doubles again between 12 and 24 months. The expanding brain creates separating tensional forces in the cranial sutures. The cranial sutures allow for skull deformation during birth and expansion during brain growth. The metopic suture normally starts to close at the age of 2 years. The sagittal suture begins to close after the age of 22 years, the coronal suture after 24 years, and the lambdoid after 26 years. It is within the normal range for them not to fully close until the age of 40 years.⁶

Craniosynostosis: overview

Craniosynostosis, or the premature fusion of one or more cranial sutures, occurs in approximately one in 2000–2500 live births.⁹ It usually results in a change in head shape, and can have functional consequences. Sagittal synostosis is the most common type and is seen in 40–55% of non-syndromic cases.⁹ Coronal synostosis is the second most common (20–25%), followed by metopic synostosis (5–15%); lambdoid synostosis is rare (>5%).⁹ More than one suture is affected in 5–15% of cases.⁹ Recent studies have shown that there has been an increase in the absolute numbers of patients with sagittal and metopic synostosis in the last decade.^{10–14} Metopic synostosis is also becoming

Scaphocephaly

Figure 21.1 Skull growth in sagittal synostosis causes scaphocephaly.

more common.^{10,12,15} Craniosynostosis usually occurs as an isolated condition but can also be associated with more than 160 syndromes.¹⁶ Physical findings can include calvarial and facial dysmorphism, midface hypoplasia, hydrocephalus, deafness, blindness, mental retardation and extremity anomalies.

Classification of craniosynostosis

Primary

- Non-syndromic: sagittal, coronal, metopic, lambdoid, multi-suture
- Syndromic: Crouzon, Apert, Pfeiffer, Saethre–Chotzen, etc.

Secondary

- Metabolic disorder (e.g. hyperthyroidism)
- Malformations (e.g. holoprosencephaly, microcephaly, shunted hydrocephalus, encephalocele)
- Exposure of fetus to teratogenic drugs (e.g. sodium valproate, phenytoin, retinoic acid)
- Mucopolysaccharidosis (e.g. Hurler syndrome, Morquio syndrome)

Molecular mechanisms involved in craniosynostosis

There is good evidence that the primary pathology in craniosynostosis is within the dura mater and not within the bone.^{17–20} Cranial suture fusion and maintenance of patency are dependent on the interplay of transcription factors, cytokines, growth factor receptors, and extracellular matrix molecules. It is now known that the majority of the craniosynostosis syndromes are caused by mutations in genes encoding FGFR-1 (fibroblast growth factor

receptor-1), FGFR-2 and FGFR-3, and the transcription factors TWIST (upstream regulator of FGFRs) and MSX2.^{21,22} Gain-of-function mutations are associated with the human *MSX2* and *FGFR* genes, whereas loss of function is associated with the *TWIST* gene^{21,22} (for a review see Slater *et al.*⁷). Syndromic craniosynostoses exhibit variable clinical and genetic heterogeneity. Recent advances in molecular genetics have led to a discovery of other genes implicated in different craniosynostosis syndromes^{23,24} (Table 21.1).

Mutations in *FGFR2* are the prevalent cause for three overlapping syndromes: Apert syndrome (MIM #101200), Pfeiffer syndrome (MIM #101600) and Crouzon syndrome (MIM #123500).^{23,25–32} These syndromes are characterized by craniosynostosis and varying limb malformations (i.e. midface hypoplasia and complex syndactyly in Apert syndrome, midface hypoplasia, broadened thumbs and big toes, and variable cutaneous syndactyly in Pfeiffer syndrome and facial but no limb abnormalities in Crouzon syndrome).

Parameters of care for craniosynostosis

A multidisciplinary meeting was held in March 2010 in Atlanta, Georgia with the goal of creating parameters of care for individuals with craniosynostosis from the current state of knowledge.^{33–35} These helpful documents set out a team-based approach to the diagnosis, management and treatment of craniosynostosis. Interdisciplinary craniofacial teams are commonly composed of members with expertise in anaesthesia, craniofacial surgery, dentistry, genetics, hand surgery, intensive care, neurosurgery, nursing, ophthalmology, oral and maxillofacial surgery, orthodontics, otolaryngology, paediatrics, prosthodontics, psychology,

Table 21.1 Common gene mutations in craniosynostosis

Syndrome	Causative gene	Inheritance	Clinical features	OMIM reference
Apert syndrome	<i>FGFR2</i> (10q26.13)	Autosomal dominant	Craniosynostosis (usually bicoronal), midface hypoplasia, shallow orbits, beaked nose, hearing loss, complex acrosyndactyly of hands and feet	MIM #101200
Crouzon syndrome	<i>FGFR2</i> (10q26.13)	Autosomal dominant	Craniosynostosis (usually bicoronal), midface hypoplasia, shallow orbits, hearing loss	MIM #123500
Crouzon syndrome with acanthosis nigricans	<i>FGFR3</i> (4p16.3)	Autosomal dominant	Craniosynostosis (usually bicoronal), midface hypoplasia, shallow orbits, hearing loss, acanthosis nigricans	MIM #612247
Pfeiffer syndrome	<i>FGFR1</i> (8p11.23–p11.22) <i>FGFR2</i> (10q26.13)	Autosomal dominant	Craniosynostosis (usually bicoronal), midface hypoplasia, shallow orbits, hearing loss, broad radially deviated thumbs/great toes, partial syndactyly of fingers and toes	MIM #101600
Muenke syndrome	<i>FGFR3</i> (4p16.3) specific mutation Pro250Arg (P250R)	Autosomal dominant	Craniosynostosis (usually bicoronal or unicoronal), midface hypoplasia, hearing loss, variable and low penetrance limb malformations	MIM #602849
Saethre–Chotzen syndrome	<i>TWIST1</i> (7p21.1); <i>FGFR2</i> (10q26.13)	Autosomal dominant	Craniosynostosis (usually bicoronal), syndactyly, congenital heart defects, low frontal hairline, ptosis, small ears with prominent horizontal crurae	MIM #101400
Antley–Bixler syndrome without genital anomalies or disordered steroidogenesis	<i>FGFR2</i> (10q26.13)	Autosomal recessive	Craniosynostosis (usually bicoronal), radiohumeral synostosis, osteodysgenesis, long bone fractures	MIM #207410
Antley–Bixler syndrome with genital anomalies and disordered steroidogenesis	<i>POR</i> (7q11.23)	Autosomal recessive	Craniosynostosis (usually bicoronal), radiohumeral synostosis, genitourinary anomalies, adrenal insufficiency and Addisonian crisis	MIM #201750
Greig cephalopolysyndactyly	<i>GLI3</i> (7p14.1)	Autosomal dominant	Frontal bossing, scaphocephaly, hypertelorism, pre- and postaxial polydactyly and variable syndactyly. Variable phenotype and can include craniosynostosis	MIM #175700
Craniofrontonasal syndrome	<i>EFNB1</i> (Xq13.1), genetic heterogeneity	X-linked	Paradoxically greater severity in heterozygous females than in hemizygous males. Females have frontonasal dysplasia, craniofacial asymmetry, craniosynostosis, bifid nasal tip, longitudinally grooved nails, wiry hair, and abnormalities of the thoracic skeleton, whereas males typically show only hypertelorism	MIM #304110
Carpenter syndrome	<i>RAB23</i> (6p11.2)	Autosomal recessive	Acrocephaly with variable synostosis of the sagittal, lambdoid, and coronal sutures; peculiar facies; brachydactyly of the hands with syndactyly; preaxial polydactyly and syndactyly of the feet; congenital heart defects; growth retardation; mental retardation; hypogenitalism; and obesity. Cerebral malformations, oral and dental abnormalities, coxa valga, genu valgum, hydronephrosis, precocious puberty, hearing loss	MIM #201000
Beare–Stevenson cutis gyrata	<i>FGFR2</i> (10q26.13)	Autosomal dominant	Craniosynostosis, cloverleaf skull. Cutis gyrata variably affects scalp, forehead, face, preauricular area, neck, trunk, hands, and feet. Acanthosis nigricans	MIM #123790

public health, radiology, social work and speech–language pathology. Ideally, care for patients with craniofacial anomalies is best provided in craniofacial centres by a dedicated team of specialists who see a sufficient number of affected patients to understand the management of complexities. It is important to assess a child with craniosynostosis early and this should begin perinatally.

Prenatal diagnosis

Cranial sutures form at about 16 weeks' gestation. Antenatal ultrasound scans are commonly performed at 20 weeks' gestation and therefore there has not been enough time for growth distortion of the skull to have occurred except in the most severe cases.²³ Most patients with craniosynostosis are not detected during pregnancy.

Craniofacial assessment

Initial history and examination from birth to age

3 months

The aims are: (a) to determine whether craniosynostosis is present; (b) to determine whether there are additional features suggesting an associated syndrome and (c) to assess whether urgent or elective management is required. Craniosynostosis is very heterogeneous in its causes and presentation, and therefore in its management. Most isolated non-syndromic cases present electively, but a minority of syndromic cases present acutely and require immediate intervention.

Questions should be asked about any identifiable causes, such as intrauterine constraint (primiparity, multiple pregnancy, abnormal lie, oligohydramnios),³⁶ teratogenic exposure (e.g. maternal use of oral retinoids, sodium valproate or phenytoin during pregnancy), family history of abnormal head shape and genetic abnormalities. Questions should include whether the conception was normal or assisted, whether the pregnancy was normal, birth history and birth weight. The child's current weight and birth weight should be plotted on a growth chart. Questions must be asked about the airway, feeding, eye protection and elevated intracranial pressure (ICP). It is important to look for evidence of breathing difficulty, choking or vomiting on feeds, failure of eyelids to cover eyes during sleep, or irritability, as these may be indications for acute intervention.

The most common presentation is with an unusual head shape. The head may be long and narrow (scaphocephaly, dolichocephaly), triangular at the front (trigonocephaly), broad and flattened (brachycephaly) or skewed (plagiocephaly). The clinician should examine the hands and feet, looking for congenital anomalies, for example, a broad, radially deviated thumb or big toe in Pfeiffer syndrome, complex syndactyly in Apert syndrome and longitudinally split nails in craniofrontonasal syndrome. The face should be examined for dysmorphic features, including hyper- or hypotelorism, exorbitism, midface hypoplasia, facial asymmetry, ear size, ear position and shape. The skull shape should be examined from the front, back, sides and top. The sutures should be palpated for ridging (associated

with suture fusion). The size, shape and tension of the fontanelles should be assessed. The head circumference should be measured and plotted on the growth chart. The cephalic index (ratio of maximum breadth to maximum length of skull, normally between 0.76 and 0.83 (in boys) or 0.84 (in girls)) provides an objective measurement and requires calipers. Examine the mouth for a cleft palate and a complete general physical examination, including that of the cardiovascular system. Patients should also have an eye evaluation with a fundoscopic examination and visual evoked potentials (VEPs) can be useful.^{37,38} The patient should be reviewed by the genetics team, paediatricians, audiology and ENT. Hearing problems are common. The speech and language team should assess feeding and swallowing. Clinical 2D (and if possible 3D) photographs and further radiological imaging are performed as necessary. The parents should be assessed to see if they have any features suggestive of craniosynostosis.

Deformational posterior plagiocephaly

Craniosynostosis must be differentiated from deformational plagiocephaly, which has become increasingly common after the American Academy of Pediatrics Task Force on Infant Positioning and Sudden Infant Death Syndrome (SIDS) recommended in 1992 that healthy infants be positioned on the back or side, when the child is laid to sleep.³⁹ This 'Back to Sleep' campaign resulted in a dramatic decrease in the incidence of SIDS from 1.2/1000 live births in 1992 to 0.56/1000 in 2001.^{40–42} The skull of a newborn baby is malleable and the back of the head can flatten and cause associated changes in the head shape, which include ipsilateral occipitoparietal flattening on the side where the child tends to lie and apply pressure to the back of the head, ipsilateral frontal bossing and ipsilateral anterior displacement of the ear and contralateral occipital bossing (Figure 21.2).

This deformational plagiocephaly (twisted skull shape) needs to be differentiated from plagiocephaly due to other causes, which can include anterior synostotic plagiocephaly due to unicoronal synostosis, or posterior synostotic plagiocephaly due to lambdoid synostosis (Figure 21.3). Other causes of deformational plagiocephaly include intrauterine constraint (e.g. twin pregnancy), assisted delivery (e.g. forceps) and prematurity. If a child has a deformational plagiocephaly, the skull is often parallelogram shaped when viewed from above, whereas a child with a unilateral synostosis has a failure of growth on one side of the head and so the head shape will tend to be trapezoidal shaped (Figure 21.3).

In a child with a deformational plagiocephaly, the distance from the lateral canthus to the root of the helix will be the same on both sides. In a child with a unicoronal synostosis, this distance will be shorter on the affected side due to a lack of growth. In clinical practice, difficulty most commonly arises in differentiating positional plagiocephaly from lambdoid synostosis, because the changes in orbital shape and forehead symmetry are quite distinctive in unicoronal synostosis. An anteroposterior and lateral skull X-ray can be helpful to exclude a closed cranial suture. If doubt remains, referral to a specialist craniofacial unit is recommended.

Figure 21.2 Deformational posterior plagiocephaly.

Figure 21.3 Comparison of deformational posterior plagiocephaly and unicoronal craniosynostosis, which causes synostotic anterior plagiocephaly, and unilateral lambdoid synostosis, which causes synostotic posterior plagiocephaly.

Children with deformational plagiocephaly can be initially managed conservatively by turning the head, using supportive pillows, and advice about spending at least 30 min per day of 'tummy time' while the child is awake.⁴² Children should not be kept in one position for a long time, for example in a car seat or carry cot. For infants who fail to improve with repositioning by six months of age and who continue to have severe deformity,

another option is to use a moulding helmet or cranial orthosis.⁴³ The use of moulding helmets is controversial and expensive. For a review of the management of deformational plagiocephaly see Robinson and Proctor⁴³ and Losee and Mason.⁴⁴ There is some evidence that there is an increased prevalence of mild developmental delay in motor development in children with deformational plagiocephaly.^{45–48}

Radiographic imaging

Computed tomography

In cases of single suture synostosis and non-syndromic craniosynostosis, CT scanning and three-dimensional reconstruction using both bone and soft tissue windows is the most useful investigation to examine the patency of each cranial suture.⁴⁹ In patients with complex multisuture craniosynostosis or syndromic craniosynostosis, MRI can be useful to examine the intracranial anatomy in more detail, but it is less good at visualizing the cranial sutures. The brain should be examined to look for anatomical abnormalities (e.g. ventriculomegaly, Chiari malformation, syrinx, agenesis of the corpus callosum) and to assess craniocerebral disproportion.

Sagittal synostosis

This is the commonest of the craniosynostoses (40–60%). Nearly 80% of the sagittal synostoses are non-syndromic and 6% run in families with dominant transmission. It is commoner in males (3.5 : 1), and the prevalence is nearly one in 5000 children. There is growth inhibition in a perpendicular direction to the affected suture leading to a skull shape that is elongated in an anteroposterior direction, causing a boat-shaped appearance (scaphocephaly). There is sagittal ridging, frontal bossing, and a wide interorbital distance due to the unrestricted growth of the patent coronal and metopic sutures. The unrestricted growth at the lambdoid suture causes occipital bulging. The skull base is not involved. Patients with scaphocephaly can present with other clinical signs, such as cerebral palsy, psychomotor retardation, or neurological signs. Elevated ICP is seen in 7–13% of the cases. 3D CT shows suture absence, which may be focal or generalized. It can also be associated with fusion of the metopic suture⁵⁰ (Figure 21.1).

Metopic synostosis

The suture closure starts in the third trimester at the level of the glabella moving upwards towards the anterior fontanelle, and is usually fused by the ninth month, but it may take up to 2 years to fuse. Premature fusion of the metopic suture causes a triangular-shaped head or trigonocephaly (Figure 21.4). There usually is associated hypotelorism. An omega-shaped notch is commonly seen on an axial CT scan in metopic synostosis and this notch is not seen in normal patients. Patients with metopic synostosis can also have midline and forebrain abnormalities. Nearly 75% of the cases identified postnatally are isolated, with 25% being syndromic. Associated syndromes include Jacobsen/11q23 deletion, chromosome 9p deletion, and Opitz C syndrome.

Unicoronal synostosis

This accounts for around 20–30% of craniosynostosis and occurs slightly more often in girls than boys. It was thought to be non-syndromic until the association of the *TWIST1* and Pro250Arg *FGFR3* gene mutations were discovered in some cases.⁵¹ There is

Figure 21.4 Metopic synostosis causing trigonocephaly.

reduced growth on the affected side, which results in flattening of the ipsilateral frontal and parietal bones. There is posterior displacement of the calvarium and resultant superior displacement of the ipsilateral orbital roof and the lesser wing of the sphenoid bone. This results in the 'Harlequin' deformity of the orbit. There is compensatory bulging of the frontal and temporal regions on the side opposite the deformity (Figure 21.3) with anterior displacement of the sphenoid wing and ipsilateral petrous ridge.

Bicoronal synostosis

This is commonly seen in syndromic craniosynostosis and patients present with brachycephaly. The forehead is large and flat. Bicoronal synostosis is commonly seen in with Pro250Arg *FGFR3* gene mutations, where it frequently presents as an isolated feature. In other types of syndromic craniosynostosis, bicoronal synostosis is commonly found in association with midfacial hypoplasia and additional sutural fusions.

Lambdoid synostosis

Lambdoid suture synostosis is a rare form of craniosynostosis with a prevalence of <5% of all craniosynostoses. Unilateral lambdoid synostosis needs to be carefully differentiated from posterior plagiocephaly, as the management of the two conditions is completely different. On imaging there is obliteration or sclerosis of the lambdoid suture. Unilateral lambdoid synostosis creates a trapezoid-shaped head (Figure 21.3). There is ipsilateral occipitoparietal flattening and compensatory growth causing contralateral parietal and frontal bossing, and also ipsilateral occipitomastoid bossing. The ipsilateral ear may be posteriorly displaced.

Multisuture synostosis and cloverleaf skull

Most multiple suture synostoses are associated with syndromes. Common combinations include bilateral coronal with bilateral lambdoid synostoses or bilateral coronal synostoses with sagittal synostoses. When there is pansynostosis, the membranous bones of the calvarium expand between the sutures and give the appearance of a cloverleaf skull or Kleeblattschädel.

Treatment of non-syndromic craniosynostosis

The philosophy of care is a multidisciplinary team approach to correct anatomical deformity in a single stage and monitor for postoperative elevated intracranial pressure.

Most patients with an isolated single suture craniosynostosis have few problems, once this is corrected. With the exception of sagittal synostosis, which is generally treated early, most craniofacial centres treat unsutural synostosis with some form of formal calvarial remodelling to produce a definitive correction of head shape. Opinions on ideal timing vary, but in general the operation is undertaken between six months and 2 years of age. Our protocol is to monitor these patients postoperatively with an annual eye evaluation to look for signs of elevated ICP.

Genetic testing of non-syndromic craniosynostosis patients has led to the discovery of associated genetic mutations. Patients have increased levels of autism and learning difficulties compared to their peers and this may not necessarily be related to elevated ICP. It is thought that up to 15% of patients with non-syndromic craniosynostosis will develop elevated ICP.^{52,53}

For patients with single-suture non-syndromic craniosynostosis, specific operations have been developed that are tailored to correct the characteristic head shapes and these are summarized below:

Sagittal synostosis

Patients can undergo surgery from about four months of age, which involves excision or release of the sagittal synostotic suture and then a device can be applied to mould the head shape. This can be done via an endoscopic-assisted suturectomy, with or without an orthotic helmet moulding device. The other main technique is to use a springs-assisted cranioplasty, which can be performed before six months of age. Two parasagittal osteotomies are made via a short coronal incision on the vertex. The bone with the fused sagittal suture is left intact over the sagittal sinus and three or four stainless steel springs are inserted into the edges of the osteotomies and they push the bone edges apart and remodel the head shape (Figure 21.5). The springs are removed a few months later at a second operation.

Older children between 9 and 18 months of age will need more extensive surgery, for example the Pi procedure (Figure 21.6). A total calvarial remodelling is indicated for a child who presents later, from the age of 18 months onwards. Patients will need pre-operative eye evaluation to look for signs of elevated ICP and will

Spring assisted cranioplasty

Figure 21.5 Springs-assisted cranioplasty for sagittal synostosis.

also need monitoring postoperatively as a small percentage of patients develop elevated ICP after surgery.

Fronto-orbital advancement

Patients with metopic synostosis, unicoronal synostosis and bicoronal synostosis require an operation to correct the shape of the supraorbital and frontal region. Surgery to correct these craniosynostoses involves different types of fronto-orbital advancement (Figure 21.7).

A fronto-orbital advancement is usually carried out at approximately 9–18 months of age unless signs of elevated ICP are identified earlier. The goals are to provide improved morphology of the forehead and upper orbits and, where necessary, increased intracranial space in the anterior cranial vault for the brain and increased orbital volume, which allows the eyes to be positioned more normally for better protection from exposure.

A coronal (scalp) incision is made, and the anterior flap is elevated either in a subgaleal plane or subperiosteally along with the temporalis muscle. The degree of further dissection depends on the extent of planned surgery. The most common procedures undertaken remodel the fronto-orbital bar (Figure 21.7). At Great Ormond Street Hospital, we favour a much more limited procedure which does not remodel the entire fronto-orbital bar. This limits the amount of orbital dissection required.

A frontal craniotomy is then performed. This allows retraction of the brain so that any orbital osteotomies can be safely undertaken and harvests the frontal bone, which will be reshaped during the procedure.

To undertake a traditional fronto-orbital remodelling, orbital osteotomies are completed across the orbital roof and superior

Procedure

Figure 21.6 Pi procedure for the treatment of sagittal synostosis.

Fronto-orbital advancement

Figure 21.7 Fronto-orbital advancement.

aspect of the medial orbital wall, laterally through the lateral orbital wall and inferiorly just into the inferior orbital fissure. The three-quarters orbital osteotomy units are removed from the field and reshaped and then re-inset. The supraorbital bar is overcorrected. Fixation is generally achieved with resorbable sutures and plates and screws or stainless steel wires. Calvarial bone is cut into segments, which are replaced as grafts to achieve a more normal appearance of the anterior cranial vault.⁵⁴

Posterior cranial vault remodelling

Patients with either unilateral or bilateral lambdoid synostosis benefit from posterior cranial vault remodelling. It is also beneficial in patients with syndromic craniosynostosis who have a bicoronal synostosis and craniocerebral disproportion, and elevated ICP as it leads to an increase in the size of the volume of the skull. It can be performed with or without distractors or springs depending on the requirements of the individual patient. It can also be helpful to correct a Chiari I malformation.⁵⁵

Treatment of syndromic craniosynostosis

The philosophy of care is a multidisciplinary team approach to maximize developmental potential, with staged operations and follow-up into adulthood.

The primary aim of treatment is the prevention and treatment of functional morbidity due to potential problems with vision, airway, elevated ICP, hearing, nutrition, psychological and social development, which can all contribute to developmental delay (Figure 21.8).

Crouzon syndrome

In 1912, Crouzon described a condition featuring craniosynostosis, maxillary hypoplasia, exorbitism, class III malocclusion and hypertelorism.⁵⁶ The hands and feet are usually normal, but subtle anomalies can occur. Crouzon syndrome represents 4.8% of cases of craniosynostosis at birth and the birth prevalence has been estimated to be 16.5 per million births. The syndrome is caused by a genetic mutation generally in the *FGFR2* gene and

Figure 21.8 Functional problems in syndromic craniosynostosis which contribute to developmental delay.

can arise *de novo* or is inherited in an autosomal dominant fashion. Older paternal age is a risk factor for a *de novo* mutation.⁵⁷ The phenotype can be variable in severity and craniosynostosis can be absent or delayed.⁵⁸ Both coronal sutures are commonly fused, but the sagittal and lambdoid sutures can also be involved. The anterior and posterior cranial base can be short due to early closure of the basicranial synchondroses and thus the posterior fossa is often shallow and cerebellar tonsillar herniation can occur, as well as elevated ICP. The volume of the nasopharynx is also reduced, which can contribute to obstructive sleep apnoea (OSA).

Apert syndrome

In 1906, Apert reported a series of cases with a brachycephalic head, severe syndactyly of hands and feet and a cleft palate.⁵⁹ Apert syndrome or acrocephalosyndactyly type I is characterized by craniosynostosis, turribrachycephaly, hypertelorism, downslanting palpebral fissures, exorbitism, midface hypoplasia, class III malocclusion, cleft palate and complex syndactyly of the hands and feet. Apert syndrome represents 4.5% of all craniosynostosis cases and the birth prevalence is 15.5 per 1 million births.⁵⁸ The syndrome is caused by a one of two *FGFR2* (10q26.13) mutations involving amino acids (Ser252Trp and Pro253Arg), and can arise *de novo* or is inherited in an autosomal dominant fashion. Older paternal age is a risk factor for a *de novo* mutation.⁵⁷ The anterior cranial fossa is shortened and widened and the orbital volume is reduced, causing exorbitism. There is a wide-open calvarial defect from the root of the nose to the posterior fontanelle in the mid-sagittal plane. The intracranial volume is increased compared to controls. Cloverleaf skull has been reported in association with Apert syndrome and occurs in about 4% of cases. Globe subluxation can occur. Cleft palate commonly occurs and the palate is high arched, with an anterior open bite and dental overcrowding. There is no association with cleft lip. Upton described a classification of the Apert hand (Table 21.2).⁶⁰ Additional anomalies can include fusion and malformation of other joints, including the elbows and shoulders, cervical vertebral fusions, congenital airway malformations, deafness and neurodevelopmental abnormalities. There is a greater downward slant of the lateral canthi and a distinctive, S-shaped upper eyelid ptosis. The quality of the skin frequently varies from normal, with acne and hyperhidrosis being prominent features.

Pfeiffer syndrome

The original report of Pfeiffer syndrome in 1964 described a family of three generations in whom eight individuals had a syndrome consisting of cranial vault abnormalities, broad thumbs and great toes and partial syndactyly of the hands and feet.⁶¹ Additional anomalies can include ankylosis of the elbow and other joints, congenital airway malformations, deafness and neurodevelopmental abnormalities.⁶² There is a characteristic facial appearance: a wide cranial vault with a flat occiput, broad high forehead, midface hypoplasia, a small nose with a depressed nasal bridge and orbital hypertelorism. Patients often have exorbitism due to shallow orbits. It affects approximately 1 in 100 000 individuals.⁶³ The syndrome may be caused by mutations in the fibroblast growth factor genes *FGFR1* (chromosome 8p11.2–p11)⁶⁴ or *FGFR2* (chromosome 10q26.13).^{65,66} The mutation can arise *de novo* but can also be inherited in an autosomal dominant fashion. Males and females are affected equally. The spontaneous mutation is thought to be associated with advanced paternal age.⁵⁷ Pfeiffer syndrome is considered type V of the acrocephalosyndactyly syndromes.⁶³ Respiratory, ocular, otologic and neurologic problems are key factors for these patients and indicators of the need for treatment.

Functional problems associated with syndromic craniosynostosis

Neurological problems

Elevated intracranial pressure is a serious functional problem. It can have a slow onset and be difficult to recognize in a paediatric population. Untreated craniosynostosis with elevated ICP will cause papilloedema and eventually optic nerve atrophy and blindness. There is no consensus on what normal levels of ICP are in a paediatric population, as this is not routinely measured in healthy children. Elevated ICP results from a number of different factors, including craniocerebral disproportion, abnormalities of cerebrospinal fluid dynamics, impaired cerebral venous drainage secondary to generalized cranial base stenosis and hydrocephalus.^{54,67}

Hydrocephalus is common and is characterized by a progressive enlargement of the ventricles over time, which is different from non-progressive ventriculomegaly related to brain maldevelopment.⁶⁸ There is good evidence that OSA secondary to upper airway obstruction and venous hypertension exacerbate elevated ICP in patients with syndromic craniosynostosis.^{69,70}

Table 21.2 Upton's classification of the Apert hand (1991)

Deformity	Type I	Type II 'Mitten hand'	Type III 'Hoof hand'
Thumb radial clinodactyly	Present	Present	Present
Index radial clinodactyly	Absent	Present	Present
First web syndactyly	Simple (non-osseous)	Simple (non-osseous)	Complex (osseous)
Complex 2–3–4 syndactyly and symbrachyphalangism	Present	Present	Present
4–5 Syndactyly	Simple, incomplete	Simple, incomplete	Simple, complete

Source: Upton, 1991.⁶⁰ Reproduced with permission of Elsevier.

The Chiari I malformation (cerebellar tonsillar herniation) is often found in patients with syndromic craniosynostosis and has a mechanical rather than developmental aetiology and can be caused by a small posterior fossa (which in itself could be due to lambdoid suture fusion) or by venous congestion because of obstruction to venous outflow across the abnormal skull base.^{70,71} Brain anomalies that can occur include: defects of the corpus callosum, porencephalic cysts, mega cisterna magna, focal cortical tissue loss and brain herniation through multiple areas of the skull base due to elevated ICP.⁷²

Patients with Crouzon syndrome usually have normal intelligence, with about 3% having intellectual compromise.⁷³ Patients with a mild Apert or Pfeiffer phenotype can have normal intelligence and those with a severe phenotype can have severe neurodevelopmental delay.^{58,74}

Ocular problems

Primary ophthalmic findings in Apert, Crouzon and Pfeiffer syndromes include exorbitism due to shallow orbits, increased interpupillary distance, strabismus, refractive error, iris colobomata, cataracts, nasolacrimal duct obstruction and ptosis. Secondary findings include amblyopia, corneal exposure, globe herniation, optic atrophy and papilloedema.⁷⁵ Major causes of visual loss are amblyopia, exposure keratopathy and optic atrophy, due to elevated ICP.⁷⁶ Patients with syndromic craniosynostosis must undergo regular ophthalmologic assessment.

Otological problems

Hearing loss is common. External auditory canal anomalies can occur, with stenosis or atresia of either the bony or cartilaginous parts of the auditory canal, and malformations of the middle ear and ossicles,⁷⁷ with concomitant conductive hearing loss. CT scanning can be helpful in defining the anatomical abnormalities.⁷⁸ There is a higher incidence of middle ear effusions in patients with Apert syndrome, which may be related to the presence of a cleft palate.⁷⁹

Respiratory problems

Airway pathology can include midface hypoplasia, nasopharyngeal stenosis, choanal atresia or stenosis, and tracheal anomalies.^{73,74,80,81} These represent a significant source of potential morbidity and mortality. Airway obstruction can cause failure to thrive, suboptimal neurological development and developmental delay. Disruption of sleep states in OSA, particularly loss of sustained quiet sleep, has been shown to impair growth hormone release.⁶⁷ There is a strong correlation between the presence of hydrocephalus requiring ventriculoperitoneal (VP) shunting and severe upper airway obstruction: 69% of patients with VP shunts also required tracheostomy.⁸⁰

Many children with syndromic craniosynostosis need some form of airway support during infancy or childhood. A drop off the growth curve can be a useful predictor of the need for both airway and feeding intervention in children with craniosynostosis.⁸⁰ A nasogastric tube or a gastrostomy tube may be required.⁵⁴ Lymphoid

hypertrophy occurs at approximately age 3–6 years and children whose airways become more obstructed at this age often benefit from tonsillectomy and adenoidectomy. Frequent monitoring for signs of upper airway obstruction is required. The use of nasopharyngeal airways, continuous positive airways pressure (CPAP) and tracheostomy may be required to maintain an adequate airway.

Congenital heart defects

It is not uncommon for children with syndromic craniosynostosis to have congenital heart defects.⁷⁴ This leads to an increased risk when undergoing surgery or general anaesthesia. Some children with congenital heart defects have the potential for either right to left or bidirectional shunts. Given that venous air embolism is common with craniosynostosis repair, the risk of coronary or cerebral air embolism is significant in these children.

Surgical management of syndromic craniosynostosis

Most children with syndromic craniosynostosis require surgery to protect function, expand the cranial vault, advance the midface and then to make final adjustments to appearance.

The management can be subdivided into 'crisis interventions' (e.g. for threats to airway, threats to vision and elevated ICP); 'early interventions' for hydrocephalus, visual disturbances, hearing deficit, OSA, which all contribute to developmental delay; interventions in childhood to change appearance in order to support psychosocial development and wellbeing and 'late interventions' to improve aesthetic appearance at the completion of growth. The sequence of surgical interventions is summarized in Table 21.3.

Management in infancy

Management in infancy is generally directed towards the treatment and prevention of functional crises. Most commonly, cranial vault expansion is undertaken to treat cranio-cerebral disproportion and elevated ICP.

Table 21.3 Sequence of craniofacial surgical procedures in syndromic craniosynostosis

Age	Procedure
6 months to 3 years	Crisis intervention (ICP, orbital protection, airway), cranial vault expansion, midfacial or frontofacial advancement
4–8 years	Correction of midface deformities, primary and secondary cranial vault procedures, and adjunctive procedures
9–12 years	Correction of midface deformities, secondary cranial vault procedures, and adjunctive procedures
13–17 years	Late correction of midface deformities. Adjunctive procedures and orthodontic therapy
Over 17 years	Orthognathic surgery

Broadly there are two philosophies of surgical management at this stage:

- A fronto-orbital advancement can be performed (Figure 21.7). Proponents of this approach cite the advantages of the increased cranial volume achieved along with some degree of orbital protection. If the frontal advancement does not relapse, midfacial advancement can be achieved at a later stage with a subcranial Le Fort III osteotomy (age 4–10 years), thus avoiding the need for a second transcranial procedure (Figure 21.9).
- The other technique is to perform a posterior vault expansion (either an acute advancement with bone grafts, or gradual advancement using springs or distraction devices). Proponents of this approach believe it is a functionally better technique, because it can produce greater increases in cranial volume than frontal advancement and there is some evidence that the change in posterior cranial fossa anatomy treats Chiari malformations. Performing a posterior expansion at this stage leaves the forehead untouched, which is a great advantage from a technical point of view if a frontofacial advancement osteotomy is required at a later date.

In children with severe exorbitism, elevated ICP and upper airway obstruction, frontofacial advancement by distraction can be considered as early as four months of age.⁹⁷

Management of midface deformity in childhood and adolescence

Severe midfacial retrusion is usually corrected in childhood or adolescence. There are two commonly adopted strategies. The first is to perform a frontofacial advancement, which is most commonly performed as a monobloc osteotomy (Figure 21.10). The osteotomy effectively cleaves the entire facial skeleton and forehead from the anterior skull base. Advancement of the monobloc segment increases intracranial volume, enlarges the

orbits, increases upper airway volume and advances the midface. The procedure can be performed conventionally holding the advanced segment in position with bone grafts, plates and screws, but is nowadays most frequently undertaken by internal or external distraction techniques (Figure 21.11). The procedure is effective and has been successfully adapted to deal with the anatomical facial flattening seen in Apert syndrome by converting the monobloc to a facial bipartition advancement.⁸²

The second strategy is to advance the forehead and midface separately in two operations (first a fronto-orbital advancement (Figure 21.7) followed at a later date by a subcranial Le Fort III osteotomy (Figure 21.9). The Le Fort III can also be performed conventionally or by distraction.

There is good evidence to suggest that frontofacial advancement produces better functional outcomes and aesthetic results than a two-stage forehead advancement and Le Fort III. The disadvantage of this approach is its higher complication rate.^{98,99} The monobloc osteotomy results in a communication between the anterior cranial fossa and upper nasal spaces, which increases the risk of ascending infection, persistent CSF leaks and mucocoele formation. A separate forehead advancement and Le Fort III procedure reduces these risks. Opinion remains divided about the best approach.

Orthognathic procedures for definitive occlusal correction

The mandible has normal growth potential in children with syndromic craniosynostosis, but the maxilla does not. This leads to a class III malocclusion, often with an anterior open bite. Although monobloc and Le Fort III procedures performed in childhood and adolescence go some way to correcting this intermaxillary discrepancy, there is often a residual class III malocclusion. A Le Fort I osteotomy often combined with a mandibular ramus osteotomy

Figure 21.9 Subcranial Le Fort III midface advancement.

Figure 21.10 Frontofacial advancement with monobloc osteotomy.

Figure 21.11 Frontofacial advancement by distraction using the external RED device.

(bimaxillary osteotomy) is generally required in combination with genioplasty. About 30% of patients with syndromic craniosynostosis require orthognathic surgery and this is carried out in conjunction with orthodontic treatment and planned for completion at the time of skeletal maturity (age 16–18 years).

Complications of surgery for syndromic craniosynostosis

Complications of craniofacial surgical procedures are listed in Table 21.4. Early series looking at complications for all types of craniofacial surgery quoted mortality rates of between 1 and 2%.^{89,90} In a more recent multicentre review, the mortality had fallen to 0.1% for transcranial procedures and 0.3% for subcranial procedures.⁹¹

These figures are similar to our own experience of a 0.11% mortality rate for all craniofacial procedures undertaken in the last 5 years.⁸³ Higher mortality rates are seen in reviews quoting complications for frontofacial advancement, demonstrating the greater risks associated with major surgery.^{83,91–94} The risk of death or significant morbidity most commonly arises from bleeding (either exsanguination or postoperative intracranial bleeding) or less commonly postoperative airway complications. Well-defined protocols and strategies for addressing perioperative blood loss are important.⁹⁴ It is our practice to routinely use a cell saver to recycle lost blood during major craniofacial procedures and run a strict protocol for blood replacement and investigation of blood loss post operatively.

Table 21.4 Complications of craniofacial surgical procedures

Early	Bleeding
	Airway
	Infection (e.g. meningitis)
	Neurosurgical (e.g. stroke, elevated ICP)
Intermediate	CSF leak ⁸³
	Bone loss (e.g. frontal bone) ^{83,84}
	Osteomyelitis/sequestrum
	Plate infections
Late	Mucocele ⁸³
	Late bone loss
	Relapse
	Seizures ^{82,83,85}
	Premature ageing ^{86,87}
	Radiation exposure from multiple CTs ⁸⁸

Conclusions

Modern craniofacial surgery, despite the risks of serious complications, has transformed the lives and developmental potential of children with syndromic craniosynostosis. The treatment of craniosynostosis requires a dedicated multidisciplinary team because of the complex interrelated functional and anatomical problems caused by the condition. It is only with the help and advice of members of this team that craniofacial surgeons can make informed decisions about the timing of surgery and the use of different surgical techniques.

CHAPTER 22

Orthognathic surgery

Tim Lloyd,¹ Ravinder Pabla,¹ Sujata Sharma² and Nigel Hunt³

¹Department of Oral and Maxillofacial Surgery, University College Hospital, London, UK

²The Eastman Dental Hospital, London, UK

³Craniofacial & Development Sciences, UCL Eastman Dental Institute, London, UK

Introduction

Orthognathic surgery involves the surgical manipulation of elements of the facial skeleton to restore anatomic proportion, facial harmony and a functional relationship in patients with dentofacial skeletal disproportion. Successful orthognathic surgery requires multidisciplinary input involving the patient, consultant orthodontists and maxillofacial surgeons, laboratory technicians and others (e.g. liaison psychiatrist, restorative dentistry consultants, dental hygienists, ENT surgeons and nurses). It is commonly used for the treatment of dentofacial discrepancies when orthodontic treatment and cosmetic procedures are insufficient to answer the patient's concerns.¹ Orthognathic surgery is involved in the final correction of syndromic craniofacial patients, congenital disorders such as hemifacial microsomia and acquired disorders such as hemifacial atrophy (Figure 22.1).

Surgery is part of a larger, more complex treatment pathway that usually involves both pre- and postsurgical orthodontics. Orthognathic treatment seems to provide good outcomes at relatively low cost.²

Indications for treatment

Treatment is indicated where a patient is handicapped as a result of dentofacial deformity. This may manifest in various ways:

- Compromised jaw function: The patient with an anterior open bite often complains that they are unable to bite into a sandwich. Improving the bite may also improve dental health.
- Discrimination due to facial and dental appearance: This may be subjective and difficult to quantify. Assessment is often helped by the involvement of a liaison psychiatrist.^{3–5}
- Sleep apnoea: Bimaxillary advancement is a recognized and effective treatment for sleep apnoea.⁶

There is no evidence that orthognathic surgery is a treatment for temporomandibular joint disorders.⁷

Treatment planning for the correction of dentofacial disproportion involves consideration of multiple variables. The ultimate aim is to address the patient's concerns and have a satisfied patient at the end of treatment.

Overall treatment aims can be broken down as follows:

- 1 Achieve optimal dental occlusion/function and harmonious, balanced facial aesthetics.
- 2 Optimize future oral health.
- 3 Minimize treatment morbidity.
- 4 Maximize the possibility of a stable result.
- 5 Eliminate other symptoms of dentofacial deformity.
- 6 Patient satisfaction.

It is important that patients prioritize what they wish to achieve and that they have realistic expectations of the likely outcomes. Patients attend a new group-style clinic⁸ where they have an opportunity to question the team and a past patient. The more informed a patient prior to commencement of treatment, the greater their likelihood of satisfaction at the end of treatment.^{1,9}

General assessment¹⁰

Clinical evaluation of the face requires that the clinician knows what to look for. Leonardo da Vinci called this 'sapre verde'.¹¹

When assessing a patient it is important to ensure that a natural head position is adopted. This is the position taken by the head when standing straight and looking into a mirror placed at eye level with the interpupillary line parallel to the floor. Assessment is undertaken by systematic examination in full face view and in profile.

Frontal facial evaluation (full face)

Facial shape

Facial index is the ratio of facial height to facial width (Figure 22.2). Facial height is the distance from trichion to soft tissue menton. Facial width is the distance between the

Figure 22.1 Pre- and post-op views of a patient treated for hemifacial atrophy.

Figure 22.2 Assessment of facial shape and vertical proportions. *H*, facial height; *W*, facial width.

lateral-most aspect of each zygomatic arch. For males, facial index should approximate to 1.35:1 and for females to 1.3:1.

Vertical proportions

These are assessed by facial trisection to upper third – hairline trichon to nasion, middle third – nasion to subnasale and lower third – subnasale to soft tissue menton (Figure 22.2). Anterior lower facial third is often slightly greater than the middle third, especially in males.

Figure 22.3 Assessment of transverse proportions and facial symmetry. Facial and maxillary midlines are demonstrated by the yellow line. Mandibular midline is indicated by the blue line.

Transverse proportions

Transverse proportions are assessed by the rule of fifths (Figure 22.3). Each fifth is approximately the width of an eye. Mouth width should be equal to the distance between the medial iris margins. Alar base width should be equal to the intercanthal distance.

Anteroposterior assessment

Increased scleral show is a sign of midface deficiency. Paranasal hollowing/flatness is a sign of maxillary hypoplasia (Figure 22.4).

Figure 22.4 Maxillary hypoplasia related paranasal hollowing (black arrows) and dark buccal corridors (blue arrows).

Facial symmetry

Facial midline is the line connecting the middle of the philtrum of the upper lip (Cupid's bow) and nasion (see Figure 22.3). Minor asymmetry is considered normal.

The transverse occlusal plane should be parallel to the interpupillary line in the absence of a transverse maxillary cant or vertical orbital dystopia. Patients with a vertical orbital dystopia will have acquired a compensatory, horizontal head tilt and this will persist after surgery.

Maxillary midline

This is assessed in relation to the middle of the philtrum of the upper lip (Cupid's bow) and facial midline (see Figure 22.3).

Mandibular midline

Mandibular dental midline is assessed in relation to the chin's midpoint and facial midline (see Figure 22.3).

Dark 'buccal corridors' on smiling

These may be due to transverse maxillary deficiency, palatally inclined maxillary posterior teeth and maxillary retrognathia (see Figure 22.4).

Maxillary incisors and upper lip

Maxillary central incisors are approximately 9–12 mm in length. Tooth show is normally 2–4 mm, at rest. Incisal edge wear reduces incisor exposure. Reduction will also occur in cases of gingival hypertrophy and with a more incisal gingival attachment.

Vertical lip position depends on upper lip length and vertical maxillary incisor position (see below). With closed lips, the lower lip should cover the incisal third of the maxillary incisors.

The relationship of the upper lip to the upper incisors helps determine adequacy of maxillary position.

Anteroposterior lip position

Lips may be:

- held together at rest and therefore termed 'competent';
- apart at rest by more than 3–4 mm but able to be closed together with conscious effort – 'potentially competent'; or
- unable to be held together due to interposed teeth or relative jaw malposition and therefore 'incompetent'.

Lip animation

A strap-like lower lip often retroclines incisors. This commonly occurs in class II division 2 cases in the presence of a deep labio-mental fold.

Lip shape

Everted lips may be due to interposed proclined maxillary incisor teeth. Flat or backward sloping lips give an 'aged' appearance to facial profile. Full lips are less likely to significantly alter position with anteroposterior dental movement. Thin lips are more likely to 'flatten' with incisor retraction. Vermillion show of the lower lip is 2–3 mm more than in the upper lip.

Upper lip length and smile curtain

Normal upper lip length is 18–22 mm. Upper lip length usually comprises one third of anterior lower face height (see Figure 22.2). An increased muscular capacity to raise the upper lip higher than average when smiling may lead to excessive show of the gingival tissues and a 'gummy smile'. If the lip–incisor relationship at rest is correct, this smile curtain may have to be accepted. The Le Fort I incision tends to reduce the smile curtain slightly, at least temporarily.

Facial profile evaluation

Anteroposterior position of maxilla

The Frankfort plane is an important cranial base reference point and is taken to represent the true horizontal (Figure 22.5). It is the plane between the superior margin of the external auditory meatus and the inferior most point of the infraorbital margin. The Frankfort plane is parallel to the floor when a patient has adopted the natural head position.

Facial vertical line is perpendicular to the Frankfort plane from soft tissue nasion, with the patient in natural head position. Subnasale is on this line.

Anteroposterior chin position

Soft tissue pogonion (i.e. most anterior point on the symphysis) should be 0 ± 2 mm to facial vertical¹² (see Figure 22.5). It is vital to assess the soft tissue thickness anterior to the bony chin, as an overprojection of the chin may be entirely due to the soft tissue thickness.

Anteroposterior lip position

The aesthetic line joins the nasal tip to soft tissue pogonion (see Figure 22.5). The upper lip should be 4 mm and the lower lip 2 mm behind this line in adults. This is very dependent on nasal and chin projection. The harmony line runs from soft tissue pogonion to touch the upper lip (see Figure 22.5). It should bisect the nose.

Relationship of upper lip to nasal columella

Nasolabial angle is formed between the nasal columella and the upper lip slope.¹² The average value ranges between 85 and 120°.

Relationship of lower lip to chin

Labiomental angle is formed between the lower lip and chin. It is determined by the lower incisor inclination and anterior lower face height.^{12–14} The average value varies between 110 and 130°.

Figure 22.5 Evaluation of facial profile.

Relationship of chin to submental plane

Lip–chin–submental plane angle averages 90–110°. This is obtuse if mandibular retrognathia, retrogenia, excessive lower lip projection or increased submental fat are present ('double chin').

Dental occlusion

A malocclusion can be defined as 'an appreciable deviation from ideal occlusion' and is described as misalignment of teeth or incorrect relation between the teeth in the two dental arches. Malocclusions may be accompanied with a skeletal discrepancy, warranting orthognathic surgery to 'normalize' the relationship between the maxilla and mandible.

Occlusion refers to the manner in which the opposing teeth meet. There are a number of ways a malocclusion may be classified including based on molar relationship (Angle's classification) and based on incisor relationship (British Standards Institute classification).

Angle's classification

This was described by Edward Angle in the 1890s and describes the molar relationship in the anterior–posterior direction between the mesiobuccal cusp of the maxillary first molar and mesiobuccal groove of the lower first molar (Figure 22.6).

The molar relationship can be class I, II or III and different molar relationships can exist on either side of the mouth.

- *Class I (neutroclusion)*: The mesiobuccal cusp of the permanent maxillary first molar occludes in the buccal groove of the permanent mandibular first molar.
- *Class II (distocclusion/post-normal)*: The mesiobuccal cusp of the permanent maxillary first molar occludes mesial to the buccal groove of the permanent mandibular first molar.
- *Class III (mesiocclusion/pre-normal)*: The mesiobuccal cusp of the permanent maxillary first molar occludes distal to the buccal groove of the permanent mandibular molar.

A half unit class II or class III molar relationship is also occasionally described.

Figure 22.6 Angle's molar relationship in the anterior–posterior direction between the mesiobuccal cusp of the maxillary first molar and mesiobuccal groove of the lower first molar. (a) Class I; (b) class II; (c) class III.

Incisor classification

The British Standards Institute describes the relationship between the lower incisor edges and the cingulum plateau of the upper central incisors when the teeth are in centric occlusion (in contact). The incisor relationship may be class I, class II division I, class II division II or class III (Figure 22.7).

- **Class I:** The lower incisor edges occlude with or lie immediately below the cingulum plateau of the upper incisors.
- **Class II:** The lower incisor edges lie posterior to the cingulum plateau.
 - Division I: The upper incisors are proclined and the overjet is usually increased.
 - Division II: The upper incisors are retroclined and the overjet is usually reduced.
- **Class III:** The lower incisor edges occlude anterior to the cingulum plateau. The overjet is reduced or reversed.

Other useful terms

Overbite is the degree of vertical overlap between the incisors when the teeth are in centric occlusion. It is measured relative to the incisor edges. Ideally, the upper incisors should overlap a third of the lower incisor crowns (Figure 22.8).

An **anterior open bite** exists when the upper incisors fail to overlap the lower incisors when the teeth are in centric occlusion.

Overjet is the horizontal overlap of the incisors. It is measured in millimetres between the labial surfaces of the upper

and lower incisors (Figure 22.9). The overjet is normally a representation of the thickness of the incisal edges (i.e. 2–4 mm). A reverse overjet exists if any of the lower incisors lie ahead of the upper incisors, leading to an anterior crossbite.

The orthognathic patient

Orthognathic surgery can be defined as ‘the correction of functional and aesthetic consequences of severe dentofacial deformity through a combination of orthodontic and surgical dentistry’. The overall treatment goal is to produce a functionally stable and balanced occlusion, in an aesthetically pleasing and harmonious face – in addition to satisfying the patient’s wishes or desires.

The patient journey

Potential orthognathic patients will often have a series of appointments prior to the commencement of orthodontic treatment (Figure 22.10). This whole journey takes approximately 2½–3 years, with, on average, 18–20 months of presurgical orthodontics followed by roughly 9–10 months of postsurgical orthodontic treatment.

The joint consultation

The patient meets the multidisciplinary orthognathic team including:

- consultant orthodontists,
- consultant maxillofacial surgeons, and
- others (e.g. liaison psychiatrist, restorative consultants, dental hygienists, ENT surgeons, nurses and lab technicians).

Factors influencing the decision to proceed with orthognathic treatment

Patient factors

Age

This influences the timing of treatment. Combined orthodontic and surgical treatment is ideally commenced on patients in whom growth has ceased. This is normally at age 18 in females and 21 in males.

Figure 22.7 Incisor relationship as described by the British Standards Institute. (a) Class I; (b) class II; (c) class III.

Figure 22.8 Overbite is measured relative to the incisor edges. (a) Deep overbite; (b) anterior open bite.

Figure 22.9 (a) Increased overjet (class II division I incisor relationship). (b) Reverse overjet (anterior crossbite).

Figure 22.10 Appointments prior to the commencement of orthodontic treatment.

- Skeletal III cases tend to get worse with growth.
- Skeletal II cases (with mandibular retrognathia) often improve with growth.
- Vertical discrepancies (e.g. anterior open bite) get worse with growth.
- Transverse discrepancies become more obvious following a growth spurt.

If orthodontic treatment in a skeletal III case commences prior to the cessation of growth, the mandible may continue to develop in the anterior-posterior direction, creating a larger skeletal III discrepancy with time. Relapse of a corrected skeletal III pattern is also often a reflection of further mandibular growth.

When there is any doubt concerning changes to the extent of a developing skeletal pattern or occlusion, the options are to:

- watch and monitor,
- take serial height measurements, or
- obtain serial records (standardized photos, radiographs and study models).

Gender

Gender will influence timing and profile considerations.

Patient complaint(s), psycho-social factors and medical history

These help identify if orthognathic treatment is suitable and will be of benefit.

Clinical factors

- Severity of skeletal discrepancy in all three planes: anterior-posterior (skeletal II or III), vertical and transverse (degree of hard and soft tissue asymmetry).
- Soft tissue findings (e.g. extraoral soft tissue asymmetry, upper lip to incisor relationship at rest and smiling, gingival show on smiling, tongue and lip activity/tone, nasio-labial angle, nasal tip elevation and alar base length).
- Dental findings, such as oral health and features of the presenting malocclusion. This includes crowding, degree of dentoalveolar compensation, presence of centreline discrepancies and arch coordination.
- Anticipated stability of any treatment options will also influence the final decision. For example, a patient presenting with a retrognathic mandible on a skeletal II base, complicated by the presence of small mandibular condyles, may benefit from an advancement genioplasty and orthodontic treatment to camouflage the skeletal II discrepancy.

Other factors

The aetiology of the presenting malocclusion and findings of other investigations (radiographic/imaging and blood test results) will also help determine the suitability of any case.

Risks of orthodontic treatment

Along with the surgical risks, all patients are informed of the following risks associated with orthodontic treatment with fixed appliances:

- **Teeth:** Decalcification (permanent scarring of teeth), root resorption (root shortening), pulpitis and devitalization of teeth (inflammatory reaction affecting nerve supply to tooth).
- **Periodontium:** Gingivitis (reversible gingival inflammation), periodontitis (gum disease), recession.
- **Other:** Dental relapse, failure to close pre-existing spaces, ankylosis (failure of a tooth to move).

Most of the dental and periodontium risks can be managed with preventative oral hygiene and dietary advice.

Presurgical orthodontics

The aims of orthodontic treatment with fixed appliances are to:

- align the arches,
- decompensate arches,
- coordinate arches, or
- facilitate segmental surgery.

Aligning the arches

The aim is to straighten the teeth and eliminate crowding. Levelling of the teeth is achieved by flattening the 'curve of spee', which describes the curvature of the mandibular occlusal plane (occlusal alignment of the teeth). In anterior open bite cases, there are two approaches that may be adopted:

- The occlusal planes may be levelled presurgically and bimaxillary surgery undertaken thereafter (a Le Fort I posterior maxillary impaction $\pm$ mandibular osteotomy).
- The arches may be aligned in segments to enable segmental maxillary surgery to correct the anterior open bite along with a mandibular osteotomy.

Decompensating the arches

Dentoalveolar compensation occurs when a mismatch between the jaws in one or more planes of space is compensated by the inclination of the teeth and may be observed in all

or some of the planes. Decompensation is undertaken to eliminate features of dentoalveolar compensation and to maximize surgical moves, enhance postsurgical aesthetics and stability of occlusion.

Anterior-posterior

In a skeletal III case, the lower incisors are often retroclined and upper incisors are proclined. Conversely, in a skeletal II case, the lower incisors may be proclined.

Decompensation puts the upper and lower incisors at the correct inclination to their respective bases and removes 'compensation' for the skeletal pattern. This makes the appearance of a pre-existing class II or III incisor relationship worse preoperatively (Figure 22.11).

Transverse

A mismatch between the position of both or either jaws may result in the development of a buccal crossbite (where the upper teeth lie in a more palatal position relative to the lowers). As a result, the upper molars may be tipped buccally and lowers lingually in an attempt to obtain some contact with each other (Figure 22.12).

Vertical

In the presence of an anterior open bite, the incisors often lie in an extruded position.

Coordination of arches

As explained above, expansion or contraction of the arches may be required to ensure the teeth intercusate and occlude appropriately once the jaws have been repositioned. Coordination of the arches is checked with serial 'SNAP impressions' of the upper and lower teeth with the fixed brace *in situ* to assess if the arches will be coordinated in all three planes.

Facilitating segmental surgery

There is normally a space requirement of 3–4 mm in between the roots and crowns of the canines and first premolars. This enables the surgeon to make the necessary cuts without damaging the teeth on either side.

Figure 22.11 Decompensation. (a) Class II division I incisor decompensation – overjet increases presurgery. (b) Class III incisor decompensation – reverse overjet increases presurgery.

Figure 22.12 (a) Rapid maxillary expansion (RME) appliance with Hyrax screw and orthodontic bands on the upper premolars and first molars. (b) Quadhelix expansion appliance with orthodontic bands on the upper first molars and palatal expansion arms.

Presurgical 'work-up'

The presurgical work-up is undertaken once the final surgical moves have been confirmed at the joint clinic consultation. At this stage the following are obtained:

- facebow record,
- impressions of the maxillary and mandibular dentition,
- occlusal registration – products such as Occlufast (a silicone-based recording material) are often used to obtain the facebow registration.

A facebow records the relationship between the maxillary dentition and condyles using 2–3 reference points. The impressions are used to cast up models of the maxillary and mandibular arches. Model surgery is subsequently undertaken enabling the fabrication of acrylic wafers (occlusal guides). In single jaw procedures, one wafer is required to relate the mobilized maxilla to the fixed mandible. In bimaxillary cases, two wafers are fabricated. The second ensures the jaws relate to each other accurately once surgery on the mandible is complete.

Ball-hooks on the orthodontic archwires enable ligation of the wafers intraoperatively and the use of elastics in the postsurgical orthodontic phase.

Postsurgical orthodontics

Patients require written and verbal support in the immediate post-op phase.

- 1 day–4 weeks post-op: Light directional (class II or III elastics) and or settling intermaxillary elastics are used to maintain or improve the final occlusion.
- One month plus: Final finishing and detailing of the occlusion is undertaken.

Surgical techniques

Le Fort I maxillary osteotomy

The Le Fort I osteotomy was initially described as an access osteotomy. In 1867, Cheever performed Le Fort I osteotomy to aid resection of nasopharyngeal masses.^{15,16} In 1926, Wassmund

described this procedure to correct dentofacial deformity. He did not complete maxillary down fracture and instead used orthopaedic traction to achieve his results.¹⁷ Auxhausen described complete mobilization of the osteotomized maxilla in 1934.¹⁸

Modern maxillary osteotomies were popularized after anatomically based work by Bell *et al.* in 1969.¹⁹ Following this work it was realized that the maxilla could be osteotomized and segmented safely with the mucosal pedicle providing the vascular supply.

Technique

The patient is carefully draped such that the whole face can be visualized (Figure 22.13). Tumescence solution is infiltrated.

Vertical maxillary dimensions are assessed with reference to a measurement against a fixed point that will not be changed by the procedure to be performed. We prefer using the medial canthus as the fixed point.²⁰ A metal ruler is used to measure the distance to the orthodontic archwire as it crosses the lateral incisor (see Figure 22.13).

An incision is made through the mucosa to bone from the midline to the anterior edge of the zygomatic buttress bilaterally. Posteriorly, the incision is angled superiorly to maintain a wide mucosal pedicle for the mobilized maxilla^{21,22} (Figure 22.14a). The flap is raised with care taken to protect the inferior orbital nerves. Anteriorly, the muscles are left attached to anterior nasal spine and the incision is made through mucosa only (Figure 22.14b). The anterior nasal spine is removed with an osteotome and remains attached to the nasal floor, muscles and septum. The floor of the nose is elevated and protected with two Howarth's periosteal elevators (Figure 22.14c). Lateral subperiosteal dissection is extended to the posterior maxilla as far as the lateral pterygoid plates.

A reciprocating saw is used to make a bone cut parallel to the occlusal plane from the maxillary tuberosity to the pyriform aperture (Figure 22.14c), remembering that the maxillary artery is related to the upper third of the pterygoid plates. A Wolford step osteotomy is a modification that could avoid a high posterior cut and avoids ramping of the maxilla.²³ A curved osteotome is used to undertake pterygomaxillary dysjunction.

Figure 22.13 Draped patient. Note exposure of whole face and intubation with a nasoendotracheal tube. Vertical maxillary reference measurement from medial canthus to archwire being taken with a metal ruler.

Finally, before down fracturing the maxilla the nasal septum and the vertical plate of the vomer are separated from the maxilla with a guarded septal chisel. The maxilla is then down fractured with finger pressure on the incisor teeth. To mobilize the maxilla a 4' × 4' Raytech gauze swab is packed posteriorly between the osteotomy cuts around the maxillary tuberosities. This not only safely strips the mucosa but also acts as a fulcrum for the application of upwards pressure on the anterior maxilla. This is a safe and effective way of stretching the soft tissues and mobilizing the maxilla. The mobilized maxilla is placed into the surgical guide and intermaxillary fixation applied (Figure 22.14d) and stabilized against the mandible in its new anterior–posterior position. The vertical position is attained either by trimming bone for an impaction or by placement of an interpositional graft for an inferior repositioning. Care needs to be taken around the floor of the nose as the pyriform aperture may require sculpting to avoid widening of the nasal base (Figure 22.14e). The septum should lie passively and, together with the inferior turbinates, may need trimming to achieve this. Adequacy of the vertical change is assessed with reference to the presurgical measurement from medial canthus to archwire.

If a segmental osteotomy is planned, segmentalization should be performed from a superior approach. Midline cuts should be made in a parasagittal position where the bone is thin and is away from the thick midline raphe, making mobilization easier.

It is important that the mandibular condyles are seated in their fossae when the maxilla is positioned and fixed. Pressure should be placed at the angle of mandible and not the chin when holding the maxillary/mandible complex in position, applying the fixation. Titanium plates are adapted to the new bony contours of maxilla and secured on each side at the nasomaxillary buttresses adjacent the pyriform rim and the zygomaticomaxillary buttresses posteriorly (Figure 22.14f). The intermaxillary fixation is released and position of the maxilla and the occlusion is checked. Closure is with 3/0 Vicryl and, if the upper lip is short, a V-Y midline closure can be used to increase lip length.

Indications

- Midfacial hypoplasia
- Maxillary excess
- Asymmetry
- Anterior open bite correction
- Transverse discrepancy.

Limitations

- Movements greater than 10 mm are difficult and potentially unstable.
- Inferior repositioning of maxilla is unstable.
- Posterior repositioning is difficult to achieve and will reduce nasopharyngeal airway space.

Versatility

- Extremely versatile, especially segmented osteotomy.

It is possible to carry out higher level maxillary osteotomies at Le Fort II, Le Fort III and transcranial monobloc levels. However, control of the occlusion and vertical position can be difficult. In 1971, Kufner described the 'quadrangular' midface osteotomy to correct asymmetry in patients with midface recession and a normal nasal skeleton.^{24,25}

Bilateral sagittal split osteotomy (BSSO)

Mandibular sagittal split ramus osteotomy can be used to correct asymmetry as well as anteroposterior discrepancies.²⁶ Since the original description, the technique has gone through a series of modifications to enable a predictable sagittal split to be achieved. The three seminal changes are the Dalpont,²⁷ Hunsuck²⁸ and Bell-Epker^{29,30} modifications.

Development of the BSSO

The original description by Trauner and Obwegeser²⁶ describes two parallel horizontal osteotomy cuts on the ramus, one lingual and above the lingula and the second buccal and below the level of the lingula in a sagittal plane.

Dalpont (1961)²⁷ overcame the problems of poor bone contact and difficulty of accessing the posterior ramus buccally by

Figure 22.14 (a) Le Fort I incision. (b) Anteriorly the incision is through mucosa only in order to maintain attachments and viability of the anterior nasal spine. (c) Howarth's elevators retracting the nasal floor as bone cuts are being made. (d) Mobilized maxilla being manoeuvred into a surgical guide/wafer. (e) Sculpting of the pyriform aperture. (f) Fixation plates *in situ*.

advancing the buccal cut to the molar region. In 1968, Hunsuck²⁸ shortened the medial cortex cut by limiting it to the mandibular foramen in the lingular fossa. Bell and Schendel (1977)²⁹ and Epker *et al.*'s (1978)³⁰ further modification involved dividing both buccal and lingual cortices at the lower border of the mandible below the anterior extension of the buccal cut, resulting in a more consistently favourable split.

With the development of piezoelectric saws and endoscopically assisted techniques Sader³¹ has reverted to the original Obwegeser procedure in certain cases, requiring small moves to benefit from the lower risk of nerve injury.

The technique

A Featherstone-type mouth gag maximizes access to the lingual aspect of the ramus. If a bimaxillary procedure is to be undertaken the mandibular bone cuts are made before commencing maxillary surgery but left incomplete so the mandible remains unsplit. The mandibular osteotomy can then be completed without the use of a mouth gag, thus avoiding undue pressure on the maxilla after it has been fixed in its new position.

An incision is made on the lateral aspect of the external oblique ridge as it begins to ascend the ramus to the level of the distal aspect of the lower first molar tooth. It is important to maintain a wide mucosal pedicle to the maxilla. From an anterior, buccal approach the temporalis muscle is stripped off the

coronoid process (Figure 22.15a). The lingual dissection starts high up on the medial ramus so that the lingula is approached from above, thus retracting and protecting the inferior alveolar nerve. The position of the mandibular foramen in the lingular fossa is indicated by the almost invariable presence of perineural and perivascular fat (Figure 22.15a). Bone cuts are made according to the Dalpont²⁷ (Figure 22.15b), Hunsuck²⁸ and Bell-Epker^{29,30} modifications with a reciprocating saw. The external oblique ridge guides the position of the cuts. The saw is placed at a 45° angle with the tip blade just above and behind the lingula. The saw cut is made in a downwards direction and continued along the inner aspect of the external oblique to the first molar region where it tapers out (Figure 22.15b). The mouth gag is removed to improve access to the lower border of the mandible. A vertical cut is made through the buccal cortex only, to join with the previously made cut. The inferior dental nerve runs in the buccal cortex in 10% of patients therefore care needs to be taken with the depth of the cut.³² Finally, a saw cut through the buccal and lingual cortex at the lower border is made.

The split is completed using osteotomes and the nerve should remain on the distal, lingual segment (Figure 22.15c).

The muscles of mastication are stripped from the lower border and medial aspect of the proximal condylar segment. Once the osteotomized segments are completely mobilized, the

Figure 22.15 Bilateral sagittal split osteotomy. (a) Ramus exposure with medial dissection exposing the perineural fat. (b) Buccal bone cut. (c) Split mandible with inferior alveolar nerve on the distal, tooth-bearing segment. (d) Completed osteotomy with bone fixation *in situ*.

distal, lingual segment is placed in the mandibular surgical guide and intermaxillary fixation is applied. If the mandible is being set back, bone is trimmed from the proximal condylar segment prior to fixation. If counterclockwise rotation of the proximal condylar segment inadvertently occurs, resultant stretch of the pterygomasseteric sling can result in instability of the osteotomy.³³ In order to avoid this, the lower borders of the mandible should be aligned across the cut separating the proximal and distal segments when fixation is applied. Lateral torque of the condyle can be a problem, particularly with rigid bicortical or lag screw fixation. Bone fixation plates (Figure 22.15d) have been designed with a degree of lateral flexibility to allow the attached muscles some degree of freedom to attain a passive condylar position within the glenoid fossae. The anaesthetic can be lightened to provide muscle tone when the fixation is being applied. The surgical guide is removed and the occlusion checked. Closure is with 3/0 Vicryl.

Indications

- Mandibular retrognathia
- Mandibular prognathia
- Mandibular asymmetries.

Limitations

- Movements greater than 10 mm are difficult and potentially unstable.
- Setback will reduce airway and tongue space.
- Unfavourable cervico-mental soft tissue changes with setback.

Versatility

- Extremely versatile and most commonly performed mandibular osteotomy.

The most common orthognathic treatment plan involves bimaxillary Le Fort I and BSSO osteotomies. Excellent results can be achieved (Figures 22.16 and 22.17).

(a)

Figure 22.17 (a) Preoperative lateral cephalometric tracing. (b) Postoperative lateral cephalometric tracing. (c) Superimposed tracings showing extent of skeletal and soft tissue changes.

Other mandibular osteotomies

Ramus osteotomies

Caldwell and Letterman (1954)³⁴ described an extra oral approach to a vertical osteotomy of the mandible allowing repositioning of the ramus under direct vision. Modern vertical subsigmoid osteotomies are performed via an intra-oral approach with fibreoptic/endoscopic guidance using an oscillating saw.³⁵ Mandibular prognathism correction is achieved with minimal risk to the inferior alveolar nerve – paraesthesia is reduced by two thirds.³⁶ It is indicated in an asymmetric move where it is important to minimize proximal segment torque. In large asymmetric moves, a vertical ramus osteotomy may be performed on one side and a sagittal split osteotomy on the side of advancement. Only small advancements of the mandible are possible when mixing these two techniques.

Total subapical osteotomy

This is indicated in cases where the discrepancy lies within the dentoalveolar segment of the mandible and the relationship of the chin to the maxilla does not require alteration. It relies on being able to exteriorize and protect the inferior alveolar neurovascular bundle. The procedure is aided by the use of a piezoelectric saw. The moves are stable as the pterygo-maxillary sling is not transgressed. It is an ideal technique for the skeletal class II patient who has an acceptably positioned chin point. At least 10mm height between the lower border of the mandible and the apices of the molar teeth is required. The bone cut should be 4mm below the root apices.³⁷

Complications

In 1998, Dimitroulis³⁸ proposed a simple classification of complications related to orthognathic surgery (Table 22.1). The important intraoperative and postoperative complications are discussed below.

Relapse

Stability can be defined as the propensity for orthodontically manoeuvred teeth and osteotomized bone segments to remain in their new positions. Relapse is a tendency to revert to pre-treatment and presurgical relations.

The keys to stable, successful treatment are:

- appropriately planned and executed orthodontic preparation;
- an understanding of the mechanisms and limitations of the adaptive processes at the bone/muscle interface; and
- an appreciation of the stability of various surgical procedures^{39,40} (Table 22.2).

Some degree of relapse is inevitable, but good orthodontic preparation can minimize and sometimes mask the extent of surgical relapse.

Condylar positioning at time of fixation is also important in stability of osteotomies. It is impossible to perfectly align the condyles to their pre-osteotomy positions, and they will thus be subject to altered loading stresses. Consequently there is always some degree of adaptation and remodelling of the condyles post surgery. The degree of remodelling will relate to stability of the orthognathic treatment. Females presenting with high maxillary-mandibular plane angle, class II division 1 malocclusion with small mandibular condyles seem to be at greater risk of

Table 22.1 Classification of complications related to orthognathic surgery

Preoperative	Intraoperative	Postoperative
Communication Diagnosis	Haemorrhage Nerve injury	Acute phase <2 weeks Chronic phase >2 weeks
Laboratory work Patient preparation	Unfavourable osteotomy Jaw malposition	Relapse Neurological dysfunction Poor aesthetics Bone healing Fixation

Table 22.2 Hierarchy of stability of surgical moves³⁹

Movement	Stability	%
Maxilla up Mandible forward ^a Chin in any direction	Very stable	>90%
Maxilla forward Maxilla asymmetric	Stable	>80%
Mandible back Mandible asymmetric move	Stable with rigid fixation	>80%
Maxilla forward and mandible back Maxilla up and mandible forward Mandible back	Unstable	Major relapse is possible
Maxilla down Maxilla wider		

^aShort and normal face height only.

condylar resorption and lysis.⁴¹ The use of bicortical position screws or lag screw techniques carry a higher risk of torquing the condyles laterally, resulting in displacement of the condyles and early disruption of the occlusion and increases relapse. The use of semirigid fixation with 2 mm mini-plates and monocortical screws reduces this risk.⁴²

Minimizing stretch of the pterygomasseteric sling is also important in maximizing stability.³³ Muscle adaptation after reattachment of the stripped tissues is a complex process and the presence or relative absence of intermediate muscle fibres seems to play a role in stability.⁴⁰

Managing anterior open bites can be challenging.⁴³ This deformity is inherently unstable after either surgical or orthodontic correction and is managed with a differential maxillary impaction creating bilateral posterior open bites which can be corrected orthodontically. The problems of pterygomasseteric sling transgression are avoided. Small anterior open bites can be managed with mandibular osteotomies and counterclockwise rotation of the distal mandibular segment using rigid bicortical fixation.

Nerve injury

A wide range of incidence in postoperative paraesthesia following orthognathic surgery has been published. In one such study, overall neurosensory deficit in a sample of 46 ramus splits at the

end of one year was 15%.⁴⁴ Another author reported 8.3% deficit at one year from 218 splits.³⁷ The severity of disturbance is closely related to the measured distance between the neurovascular bundle and the buccal cortical plate. In 91% cases with severe disturbances the distance between the inferior alveolar nerve and the buccal cortical plate was less than 1.2 mm.⁴⁵ Other variables include the degree of advancement, intraoperative bleeding, presence of wisdom teeth, bad split, nerve manipulation, rigid fixation, concomitant surgery, systemic disease and age of patient.⁶

Long-term sensory deficit occurs in approximately 10% of patients undergoing BSSO.⁴⁴ Interestingly, approximately 10% of the nerves are intimately related to the buccal cortex.^{32,36} The deficit is usually partial but can unfortunately manifest as causalgia.

Plate infection

This is a common complication and literature shows wide variation in incidence. One study suggests 13.7% of 570 cases had infected plates.⁴⁶ Mandibular plates have a higher risk of infection when compared to maxillary plates.

Bleeding

Red cell transfusion is generally not required if good technique is followed and soft tissues are handled carefully. Hypotensive anaesthesia also plays a role. Mean haemoglobin drop of just 1.7 g/dL in 82 bimaxillary osteotomy cases has been reported.⁴⁷

Other

Disastrous complications reported range from unfavourable osteotomy cuts, to bleeding from maxillary artery injury, blindness and even avascular necrosis of part or all of the jaw.⁴⁵

Advances in orthognathic surgery

Endoscopic approach and fixation

Advances in instrument development, for example, right-angled saws and screwdrivers and more widespread use of the endoscope in head and neck surgery raise the possibilities for endoscope-assisted osteotomies.⁴⁸ Possible indications might include endoscope-assisted vertical subisigmoid osteotomy in cases requiring mandibular setback where preservation of lower lip sensation is paramount. A two thirds risk reduction to the integrity of the inferior alveolar nerve can be achieved.³⁶

Piezoelectric saw

Piezoelectric, ultrasonic bone surgery systems utilize a selected frequency range between 28 and 36 kHz. They are active on mineralized tissues only, thereby limiting the risk of soft tissue injuries to anatomically important structures such as nerves, blood vessels, dura and Schneiderian membrane.

The modulated piezoelectric signal allows tissue relaxation and very high precision cutting. Narrow, smooth bone cuts in

the presence of irrigation result in less risk of hard tissue necrosis and bone trauma and allow for faster bone healing.

Piezoelectric systems are likely to take their place as technology that is complementary to manual and motorized cutting instruments. They may be of particular use in segmental osteotomies, total subapical mandibular osteotomies and also for the buccal cut in BSSO to minimize risks to the inferior alveolar nerve and adjacent teeth.³¹

Summary

An understanding of the differing abilities of patients to adapt to change, both physical and psychological, and the complex relationship of hard tissue and soft tissue changes is required to obtain optimum results in orthognathic treatment.

CHAPTER 23

Facial reanimation

Jonathan I. Leckenby^{1,2} and Adriaan O. Grobbelaar¹

¹Department of Plastic Surgery, The Royal Free Hospital, London, UK

²Department of Molecular and Cell Biology, Harvard University, Cambridge, MA, USA

Introduction

Facial paralysis presents a complex challenge to the reconstructive surgeon. Since Sir Charles Bell first described the course of the facial nerve in 1821, our understanding has led to the development of the vast array of surgical options to treat patients with facial paralysis. The fundamental problem when considering facial palsy is that there is currently no conceivable way to restore the 17 muscles of facial expression successfully. The second challenge facing the surgeon is that no patient is the same; not only the aetiology behind facial paralysis dictates which operations are available, the age group, the anatomy available and, most importantly, what the patient wants, all make the decision-making process vital.

The presentation of facial nerve paralysis also adds to the conundrum, ranging from isolated marginal branch palsy to complete bilateral palsy. The approach to the management of any patient with facial paralysis should be to break the face down into three units: the forehead, the eyes, and the mid- and lower face. In a young child, the skin quality and soft tissues are far superior to that of an elderly patient, thus problems encountered are different. Frequently, there is minimal asymmetry at rest and therefore focus needs to be directed at restoring dynamic function. In the elderly patient, skin elasticity is poorer and when combined with wasting of the soft tissues and muscles, the asymmetry at rest may be strikingly obvious and static treatment options may yield the desired outcome.

What is the importance of facial palsy reconstruction? The impact facial paralysis has on an individual can be devastating and can be broken down into functional and psychological factors.^{1,2} If a patient is unable to close their eye and the cornea is insensate, the globe will dry, leading to ulceration and ultimately blindness. Diminished oral continence, poor speech and obstructive nasal breathing are other functional problems encountered. A child who is unable to smile or convey emotion effectively may be subject to bullying and psychological trauma, and an adult with profound asymmetry at rest may be perceived as being angry, causing the patient to become socially recluse.

The aim of this chapter is to give the reader a strategy on how to approach facial paralysis. The anatomy of the facial nerve and other important structures of the face will be reviewed as this provides the foundation on which the evolutions of surgical techniques have been based. The information provided should enable a surgeon to have a methodical approach to patient management but it must be stressed that the information should be used as a guideline and that each patient will require a customized approach to a greater or lesser extent. To the reconstructive surgeon it combines the epitome of what we seek to achieve: a functional outcome where one has to consider the aesthetic result as the face is the centre of human interaction.

Anatomy of the facial nerve

The facial nerve (CN VII) develops embryologically from the second pharyngeal branchial (hyoid) arch. The motor division derives from the basal plate of the embryonic pons, whereas the sensory division arises from the cranial neural crest. The sensory portion, known as the intermediate nerve, is responsible for supplying taste to the anterior two thirds of the tongue, secretory and vasomotor fibres to the lacrimal, submandibular and sublingual glands, the mucous membranes of the nose, mouth and, finally, sensation over the external auditory meatus and posterior skin of the ear. Of clinical importance, the supranuclear innervation is bilateral to the muscles of the forehead and eyes, but only contralateral to the muscles of the lower face; this accounts for the sparing of the forehead muscles in cases of supranuclear lesions in comparison to nuclear or infranuclear lesions. The facial nerve arises from the brainstem at the junction between the pons and medulla oblongata with the intermediate nerve and is closely related to the abducens (CNVI) and vestibulocochlear nerves (CNVIII), which lie in close proximity. The course of the nerve can be simply divided into intracranial and extracranial.

Intracranial course

As the facial and intermediate nerves leave the brainstem, they course laterally towards the cranium, entering the petrous temporal bone through the internal auditory meatus, travelling with the acoustic and vestibular nerves for approximately 8–10 mm. The facial nerve then enters the fallopian canal by itself which is subdivided into three segments and is approximately 30 mm long. The labyrinthine segment is the narrowest and gives rise to the greater petrosal nerve, from the geniculate ganglion, to innervate the lacrimal gland parasympathetically. Next is the tympanic segment and the junction between the two is of clinical importance as the acute angle formed between the segments is a site where shearing can commonly occur. The mastoid segment is the third segment before the nerve arises through the stylomastoid foramen.

The second branch of the facial nerve within the facial canal is the nerve to stapedius, providing motor innervations of the stapedius muscle. The final branch is the chorda tympani, responsible for taste sensation in the anterior two thirds of the tongue; these branches are useful when examining the facial palsy patient as the clinician can determine the site of nerve injury based on end-organ functionality.

Extracranial course

After emerging from the stylomastoid foramen, the facial nerve passes through the parotid gland. The most immediate branch given off is the posterior auricular nerve, innervating the small muscles of the posterior ear and branches to the posterior belly of the digastrics muscle and stylohyoid muscle. The nerve divides into temporo-fascial and cervico-fascial divisions approximately 1.3 cm from the stylomastoid foramen. A useful clinical landmark for locating the trunk is at a point slightly anterior and inferior to the tip of the tragus; the nerve typically lies between 1 and 1.5 cm deep to this. Another consistent landmark is the course of the frontal branch, which travels from 0.5 cm below the tragus to 1.5 cm above the lateral brow.^{3,4} The zygomatic branch is frequently located 1 cm above the zygomatic arch and the buccal branch 1 cm below, whereas the marginal mandibular branch runs 1 cm below the inferior border of the mandible. The facial nerve separates into the five main branches at the pes anserinus.

The temporal branch courses cranially to cross the zygomatic arch within the superficial musculoaponeurotic system (SMAS), lying deep to frontalis but superficial to the deep temporalis fascia, coursing within or just deep to the temporoparietal fascia, SMAS continuation in the temporal region. The temporal branch is responsible for the innervation of frontalis, orbicularis oculi and corrugators supercilii. An important efferent limb from this branch is responsible for the corneal reflex.

The zygomatic branch proceeds cranially, angled towards the lateral angle of the orbit. Here it supplies the orbicularis oculi. Multiple branches passing lateral and medial to the zygomaticus major, as they radiate from the main trunk into the orbicularis oculi muscle. It is vital for not only for the

lower lid tone but also the blink reflex. This commences medially and spreads laterally.

The buccal branch is the largest branch and passes forward below the orbit and divides into deep and superficial divisions. The superficial branches lie superficial to the SMAS and supply procerus. The deep branches pass beneath zygomaticus and quadrates labii superioris, supplying them both. Further deeper branches go on to supply buccinator and orbicularis oris.

The marginal mandibular branch courses beneath the SMAS towards the chin, passing beneath depressor angulis oris (which it supplies). Here it supplies the depressor labii inferioris and mentalis.

The cervical branch is the most inferior branch and passes towards the neck over the mandible beneath the SMAS. It primarily innervates the platysma. Of the five main branches, the marginal mandibular is most susceptible to injury during facial dissection due to its variable branching pattern and the multiple procedures performed in this area.^{5,6}

There is much variability in the branching patterns of the facial nerve and numerous interconnections between them and caution must always be exerted when making a surgical approach to expose the nerve. Davis *et al.*⁷ described the multiple branching patterns of the facial nerve in 350 dissections and concluded that a consistent finding was that both frontal and marginal mandibular nerves are end-nerves.

There are 23 facial muscles, of which 17 are activated in facial expression. When considering the muscles involved with producing a smile, the most important are zygomaticus major, depressor anguli oris and the buccinators. Broadly speaking, the musculature of the face can be divided into four layers according to Freilinger⁸ from superficial to deep:

- Layer 1: Depressor anguli oris, zygomaticus minor, orbicularis oculi
- Layer 2: Depressor labii inferioris, risorius, platysma, zygomaticus major, levator labii superioris, alaeque nasi
- Layer 3: Orbicularis oris, levator labii superioris
- Layer 4: Mentalis, levator anguli oris, buccinators.

Anatomy of potential donor nerves for facial reanimation

When discussing the anatomy of the facial nerve it is worth spending some time considering other local nerves of the face. Frequently, another donor nerve is required when either there is absence of a functioning facial nerve or if it is inappropriate to consider its use. Here, three other potential donor nerves will be considered.

Masseteric nerve

The masseter is one of the principal muscles of mastication. It arises from the zygomatic arch and the maxilla and inserts into the coronoid process and the ramus of the mandible. The muscle is divided into a superficial and deep portion and is innervated

by a branch of the mandibular division of the trigeminal nerve (CN V). The masseteric nerve arises from the anterior division of the mandibular nerve, which arises from the cranium through the foramen ovale. The masseteric nerve passes laterally in front of the temporomandibular joint lying deep to the temporalis tendon. It crosses the mandibular notch with the masseteric artery and enters the masseter on its deep surface and branches within the muscle, reaching the anterior border. The nerve can be found intraoperatively by delicately spreading the muscle fibres of the masseter which are oriented downwards and backwards superficially, then downwards and forwards in the deep portion of the muscle. It is important to isolate suspected branches and use a nerve stimulator to confirm its function.

Hypoglossal nerve

The hypoglossal nerve (CN XII) nucleus is located in the medulla oblongata. It passes through the cranium to emerge from the hypoglossal canal. The extracranial course is closely related to the vagus nerve and passes between the internal carotid artery and jugular vein, lying on the carotid sheath. It passes deep to the posterior belly of the digastric muscle and enters the submandibular region, coursing lateral to the hyoglossus muscle and inferior to the lingual nerve before it branches to innervate the tongue. It innervates all of the muscles of the tongue except palatoglossus, which is innervated by the vagus nerve. When considering using the hypoglossal nerve as a potential donor nerve, it is advocated that a terminal branch is used to minimize any loss of function.

Spinal accessory nerve

The spinal accessory nerve (CN XI) is responsible for the innervation of the sternocleidomastoid and trapezius muscles. The nerve is unlike other cranial nerves in the fact it arises from the upper cervical spinal cord and enters the skull through the foramen magnum. Its intracranial course leads it to emerge from the jugular foramen. In the neck it crosses the internal jugular vein at the level of the posterior belly of digastric muscle and continues to travel caudally, piercing and supplying sternocleidomastoid and then terminating to supply trapezius.

Anatomy of potential recipient vessels for functional muscle transfers

The arterial supply of the face is predominantly via branches of the external carotid artery and the ophthalmic artery. Consideration here will be given to the branches, which arise from the external carotid artery as these are of more practical use when free muscle transfer is proposed. The three main facial arteries most suitable for arterial anastomosis are:

- the facial artery,
- the superficial temporal artery, and
- the transverse facial artery.

The facial artery arises in the carotid triangle just distally to the lingual artery behind the ramus of the mandible. It passes deep to the digastric and stylohyoid muscles and along the posterior border of the submandibular gland, superficial to the hypoglossal nerve. At the point of the antero-inferior angle of the masseter it crosses over the body of the mandible and proceeds tortuously towards the angle of the mouth. In the face it branches to give rise to the inferior and superior labial arteries and terminates as the angular artery and the lateral nasal artery.

The superficial temporal artery arises from the external carotid artery when it bifurcates to also give rise to the maxillary artery. The superficial temporal artery originates at the level of the parotid gland behind the neck of the mandible. It then courses cranially just anterior to the tragus, crossing superficially to the zygomatic process and is covered by the auricularis anterior muscle and a dense fascia. The temporal and zygomatic branches of the facial nerve cross the artery and it is accompanied closely by the auriculotemporal nerve which lies immediately posteriorly. It terminates by branching to form the parietal and frontal arteries.

The transverse facial artery arises from the superficial temporal artery before it emerges from the parotid gland. It travels transversely across the face, running between the zygomatic arch superiorly and the parotid duct inferiorly superficial to the masseter muscle.

When planning free functional muscle transfer (FFMT), good knowledge of the vascular supply is critical. Facial anatomy is by no means consistent and frequently secondary options are required; even in some cases direct end-to-side anastomosis to the external carotid artery may have to be considered and preoperative assessment with a Doppler can be helpful.

Aetiology of facial paralysis

Congenital

Birth trauma

There is an incidence of 1.8 out of every 1000 children born with facial nerve paralysis in North America.⁹ Several factors increase the chance of facial nerve injury during childbirth, including instrumentation, birth weight over 3.5 kg and primigravida. The exact mechanism of injury is unknown but likely to be caused by traction being placed on the nerve. The prognosis is excellent, with over 90% of children recovering completely without intervention.¹⁰

Mobius syndrome

Mobius syndrome is characterized by concomitant bilateral facial nerve and abducens nerve (CN VI) palsies. This leads to complete, bilateral facial paralysis leading to extreme difficulty in expressing emotion as well as oral incontinence and social ostracism.

CHARGE syndrome

The major features of CHARGE syndrome are: coloboma, chonal atresia, cranial nerve abnormalities and auditory anomalies. The minor features include distinctive facial dysmorphism, facial

clefting, tracheoesophageal fistula, congenital heart defects, genitourinary anomalies, developmental delay and short stature. Although not all anomalies may be present, at either least four major features or three major and three minor features must be present.

Hemifacial microsomia

Hemifacial microsomia covers a variety of congenital facial anomalies which arise as a lack of development of one side of the face. It is characterized by a hemifacial soft tissue deficiency and poor development of the mandible, maxilla and external ear.

Infectious

Bell's palsy

Bell's palsy represents 80% of the caseload of a facial palsy surgeon.¹¹ There is no known causative factor, although there is evidence that herpes simplex virus plays a role. Incidence is around 30 cases per 100 000 per year, and is slightly higher in pregnant women (45 per 100 000). Eighty per cent of people will completely recover within 2 years. Of the 20% remaining, the problem ranges from having a complete dense facial paralysis to synkinesis.

Ramsey–Hunt syndrome

This syndrome is caused by varicella zoster virus involving the facial nerve. It is distinguished clinically from Bell's palsy by the presence of vesicles and pain in the ear, along with a myriad of other less common symptoms. Although far less common than Bell's palsy, the prognosis is worse and most patients do not recover from the facial paralysis and develop chronic neuralgia.

Otitis media/mastoiditis

An acute infection of the middle ear or mastoid bone can very rarely lead to facial nerve paralysis. This is likely to be secondary to localized inflammation and compression of the nerve in the facial canal. Prompt recognition and treatment yields favourable outcomes and in select cases mastoidectomy may be indicated.

Cholesteatoma

A cholesteatoma is a non-malignant slow-growing skin cyst. It causes destruction of the inner ear through chronic infection and by local pressure effects as the cyst grows. Facial paralysis develops in less than 3% of cholesteatomas.

Lyme disease

Lyme disease is caused by *Borrelia burgdorferi*, which is transmitted to humans by infected ticks. The symptoms are initially non-specific, including headache, malaise and fever; however, facial paralysis can develop in up to 11% of cases. The prognosis is excellent, with more than 99% of patients going on to full recovery without surgical intervention.

Traumatic

Trauma to the face or cranium represents the second most common cause of acquired facial palsies. In blunt trauma with no associated bony involvement, the type of injury is likely to be a neuropraxia and full recovery is to be anticipated. A penetrating injury where there is a transection of the nerve warrants urgent surgical exploration and an attempt at primary nerve repair within 3 days. Beyond this the muscles can no longer be stimulated due to prolonged leakage of acetyl choline from the severed nerve ends. If the wound is grossly contaminated, it is prudent to tag the severed nerve ends, which will allow for easy identification beyond this timeframe and allow for delayed repair. When there is an injury of the temporal bone the prognosis is less favourable unless the onset of the facial palsy is delayed. In temporal fractures the incidence of associated facial nerve injury is between 5 and 10%, of which 40% will recover poorly. In this group of patients, the diagnosis of a facial nerve injury may be difficult due to other intracranial injuries, making the assessment difficult or impossible.¹² Iatrogenic injuries may occur with soft tissue, bony or intracranial surgery.

Neoplastic

The facial nerve may be prone to compression at any point along its course by a space-occupying lesion. The most common cause is secondary to compression by an acoustic neuroma followed by glomus, facial neuromas and carcinomas (skin as well as salivary gland). Manipulation of the facial nerve is frequently required in the removal of these tumours, which may lead to further injury.

Systemic and neurological

A brainstem injury may result in permanent facial paralysis due to disruption of the motor nucleus. A central facial palsy may be caused by a lacunar infarct that affects the fibres of the internal capsule going to the facial nucleus. The nucleus itself may be prone to ischaemic injury secondarily to an infarct of the pontine arteries.

Many systemic diseases may lead to facial paralysis as a consequence of disease progression. Conditions include multiple sclerosis, Guillain–Barré syndrome, autoimmune disease and diabetes. Treatment of the underlying cause is the primary management in this category.

Clinical examination

Clinical examination of the facial nerve is best undertaken in a logical routine, working from the top of the face downwards. Most pertinent information can be ascertained by observing a patient as you greet them and they talk. Resting asymmetry may be difficult to assess in the paediatric population and therefore asymmetry may only become apparent during interaction with a child and attempting to get them to smile or speak.

Beginning at the brow, look for asymmetry of the wrinkles of the forehead at rest and then ask the patient to raise their

eyebrows to exaggerate this. A particular area, which requires close examination, is the eye. Ask the patient to close their eyes as tightly as possible. The upper eyelid predominantly achieves eye closure and the lower eyelid acts to maintain the lid margins in contact with the globe and assist tear drainage. Begin with assessing the condition of the globe; for signs of epiphora, corneal irritation or ulceration. During the introductory period of the consultation it should be possible to see if the blink reflex is still intact and whether the Bell's reflex is effective. The height of the palpebral aperture should be compared between the two sides and measured during eye closure. When assessing the lower eyelid, the position of the lacrimal duct should be assessed as it normally should be lying pressed to the globe, however, when there is a moderate degree of ectropion it may be ineffective at lubricating the globe, leading to epiphora. The assessment of corneal sensation is paramount as an insensate eye, which is unable to close effectively, carries a high risk of corneal damage, ulceration and scarring which may ultimately result in blindness.

The mid-face must be examined at rest and during animation. The position of the nose, alar symmetry, the presence of a nasolabial fold, the position of the philtrum and mouth must all be noted at rest. This should be repeated while asking the patient to perform a closed mouth smile, an open mouth smile and while attempting to show all their teeth. Internal examination of the mouth is prudent as it will give the surgeon a better idea of dental hygiene and the presence of dental caries. Functional assessment of speech is performed by asking the patient to repeat labial sounds of 'b', 'p' and 'm'. Patients are also asked to pucker their lips and blow out their cheeks.

Not all patients will have a dense unilateral palsy and more subtle signs should be sought. The presence of synkinesis is particularly troublesome for patients, and the most common symptom is involuntary eye closure during smiling. Dyskinesis may also be present and signs of involuntary muscle twitching must be noted. Other potential cranial donor nerves should also be examined if relevant to the case.

A thorough discussion with the patient should then be performed if possible to elicit their symptoms. Typically this will start with the patient listing the symptoms in order of severity. In the paediatric patient this discussion mainly involves the parents and what they have noticed. It is often useful to ask the parents to bring photos or videos of the child from home as they may be somewhat apprehensive during the consultation. Parents can often feel negative emotions of guilt if their child has difficulty smiling; it is important to consider the psychological support a family may require before, during and after treatment of their child. In the adult group, they may report functional or psychological symptoms; eye-watering, drooling, difficulty eating or poor speech may be the primary concern. For some, the psychological implications of not being able to smile may be more concerning or the feeling that they are being perceived as angry or hostile may lead them to social isolation.

It is important to ascertain the patient's or parents' expectations and modify this at an early stage if appropriate. A tailor-made

patient-focused approach usually provides the most successful outcomes. After the consultation it is useful to ask the patient to have both photographic and video documentation. Each unit varies in their requirements, but this serves as a vital tool in assessing outcomes of intervention.

Many scoring systems have been proposed over time and the general consensus is that there is no ideal system. The most popular is the House–Brackmann scale, originally described in 1985 and modified in 2009 to form the basis of the Facial Nerve Grading System 2.0.¹³ It is a widely accepted system, simple, sensitive, accurate and reliable, which grades facial function in six steps from normal (HB I) to total paralysis (HB VI).

Diagnostic studies

Diagnostic studies can play a critical role in the assessment of cranial nerves either preoperatively, postoperatively or during the monitoring nerve recovery. If there is any doubt regarding a facial nerve paralysis or a potential donor nerve paralysis, it is prudent to perform further testing.

Radiological imaging in the form of a CT scan or MRI scan can be useful to exclude a space-occupying lesion. Typically this has normally been performed prior to referral. Physiological MRI scans can be used to assess cortical remodelling for situations where relearning how to use a nerve to carry out a different function needs to be assessed. If the facial palsy is part of a syndrome, it is sometimes prudent to perform an ultrasound scan to confirm the presence of a donor muscle; in second arch syndromes extensor digitorum brevis (EDB) may be absent.

Several electrophysiological tests can help guide the clinician. Electromyography (EMG) is most commonly used to assess the function of different branches of the facial nerve or potential donor nerve in comparison to the normal side. EMG is often combined with electroneurography (ENoG), which assesses nerve conductivity in comparison to muscle activity. The nerve excitability test (NET) is used mainly to determine the prognosis of nerve recovery in unilateral facial nerve palsy. The facial nerve is stimulated at the angle of the jaw with increasing current until a barely perceptible twitch is seen in the face. This is compared with the normal side and a difference of more than 2–3.5 mA is considered abnormal. Due to the invasive nature of these tests, patients may not be able to tolerate the investigation, particularly in the paediatric group.

Management

When considering the management of facial paralysis the clinician must have a set of priorities to which they adhere. First, protection of the eye is paramount. Drying out of the globe can lead to corneal ulceration and ultimately blindness if untreated. Second, oral continence and speech should be restored. Third, facial symmetry should be restored to address the aesthetic

appearance of the patient and consequently, the psychological impact of the paralysis.

Patients should be treated differently on an age criteria. In the paediatric group the eye and forehead do not usually require surgical intervention and the focus of attention should be on smile restoration. In the ageing patient, treatment options begin to become more limited as the ability of a nerve to regenerate diminishes with age as does the chance of retraining the brain if a different nerve is used. The gold standard should be to recreate symmetrical spontaneous movement; this may not be possible in all cases, and many treatment options exist to help improve the circumstance.

Broadly speaking, the management options can be broken down into non-operative and operative treatments. When considering the operative management this can further be subdivided into static or dynamic options. Static treatments will produce improve resting symmetry but cannot provide reanimation of the face, and are useful tools commonly reserved for the elderly population where skin quality is poor and there are more frequent comorbidities which exclude multiple lengthy operations. Dynamic options provide reanimation of the face and involve either local muscle transpositions or FFMTs.

Non-operative management

In cases where a spontaneous recovery is expected, this represents the mainstay of treatment. In permanent partial or complete facial paralysis, this is a key adjunct to the operative management and is by no means exclusive. In patients complaining of difficulty in eye closure at night, particularly in the absence of Bell's phenomenon, simple taping of the eyelids closed may be all that is required to relieve the symptom. It is crucial to keep the eye hydrated and this may be achieved by using topical eye-drops or lubricants.

Botulinum toxin type A provides a reversible chemical method of denervation and may be used for two different patient groups: first, in patients complaining of asymmetry and second, those complaining of synkinesis. When focusing on brow asymmetry or overactivity of the depressor, Botox is often the initial first step in a patient's management as it is minimally invasive, provides rapid visual results and is reversible. The dose is variable between patients and that it should be administered to the unaffected side when attempting to correct symmetry. Typically, patients achieve a maximum response at two weeks and the dose should be repeated every three months and titrated as necessary. Botox is effective in treating synkinesis, and the affected muscle groups may be directly injected to diminish their action. Dyskinesis is what a patient will complain of if there is involuntary twitching of muscle groups as they recover or fail to completely recovery. Botox is administered directly, typically requiring a lower dose, to the affected muscle groups and similarly repeated every three months and titrated as necessary. The key is to avoid paralyzing the muscle as this may increase asymmetry and lead to an unhappy patient outcome; if this occurs, simple reassurance is all that is required.

Operative management

Treatment in children

Since the first description of a vascularized, innervated functional muscle transfer by Harii in 1976,¹⁴ a two-stage reconstruction has become the gold standard, especially in children. In the first stage, a cross-facial nerve graft is connected to a functioning terminal branch of the facial nerve, typically a buccal branch, on the unaffected side and tunnelled subcutaneously under the upper lip to the affected side (Figure 23.1a). The donor nerve ideally should leave minimal deficit therefore a pure sensory nerve is used, usually the sural nerve from the leg. The nerve graft is then allowed to regenerate across the face, which normally takes around 3–6 months and is monitored clinically with Tinel's sign. This may be unreliable in young children as they may not fully understand the test. Also, Tinel's sign is a more sensitive indicator of sensory nerve regrowth rather than motor nerve, therefore it is important to educate the parents that this is not necessarily a sign of surgical failure. In the second stage of the surgery the patient then receives a vascularized muscle flap that will be innervated by the cross-facial nerve graft over a 6- to 12-month period (Figure 23.1b). Typical muscles used are the pectoralis minor,¹⁵ gracilis¹⁶ and latissimus dorsi, as these leave as little donor morbidity as possible. At this stage the patient will slowly regain the movement on the affected side of the face.¹⁷

In bilateral congenital facial paralysis, the facial nerve is not available as a motor nerve to drive the new muscle, therefore, a different cranial nerve may be used (e.g. V, IX or the XII). A muscle must be chosen with an appropriate pedicle length and excellent results can be obtained using latissimus dorsi or gracilis.¹⁸ This operation can be performed in one stage, with the muscle flap being raised while the face is being dissected to expose an appropriate vascular pedicle and donor nerve before proceeding to the other side (Figure 23.2). It is preferential to operate on these cases when they are young as the effect on cortical remodelling and relearning is beneficial.

When embarking on facial reanimation in children it is important to consider the impact the surgery and hospital appointments will have on a family and the child. The average time taken to complete the treatment is in the region of 2 years and this should ideally be completed before educational commitments become affected and before the child becomes fully aware of their palsy and the psychological implications begin to take hold. Surgery can be started from the age of 4 years and it is beneficial to allow time for the family to consider the surgical options in detail, therefore early referral is prudent.

Management in adults

When considering the operative management of an adult with facial paralysis it is best to think of the treatment options by breaking the face down into logical subunits consisting of the brow, the eye and the mid- and lower face, separating these into static and dynamic options.

Figure 23.1 Stage 1 and 2 facial reanimation. (a) A cross-facial nerve graft (CFNG), usually a harvested sural nerve, is joined to a functioning buccal branch of the facial nerve (FN) on the contralateral side and tunnelled subcutaneous to the preauricular area on the affected side. (b) A free functional pectoralis minor flap is raised through an axillary approach with its neurovascular pedicle. The flap is inset on the affected side where the thoraco-acromial artery and vein (A&V) are anastomosed to the facial artery and vein (FA&V) and the medial pectoral nerve is connected to the CFNG.

Figure 23.2 Mobius syndrome. (a) Preoperative photograph showing bilateral facial paralysis. (b) Postoperative photograph after bilateral facial reanimation using latissimus dorsi and the masseteric nerve.

Management of the brow

The only management options available for the brow are static; resting symmetry is the goal of treatment. Correction of brow ptosis may be approached surgically either directly or via an endoscopic approach.¹⁹ Direct brow lift incisions include brow, coronal or mid-forehead approaches. Dermadesis or a direct brow lift through a superciliary brow incision are well recognized as the favoured method in the setting of facial paralysis and can correct large discrepancies at the expense of a visible scar. An ellipse of skin and frontalis muscle is excised and pexy of orbicularis to the periosteum improves durability of the lift. The supraorbital nerve is at risk and must be carefully preserved but even so, patients often complain of numbness. A coronal brow lift is approached through an incision in the scalp 4–6 cm posterior to the anterior hairline extending to the pinna. Elevation in the subgaleal plane is performed and 1–2 cm of scalp is removed by incising anterior to the initial incision. The scars are usually inconspicuous but the amount of lifting is much less than the direct brow incision and patients often complain of paraesthesia posterior to the incision. A receding hairline, or family history of male-pattern baldness, may be a relative contraindication to a coronal brow lift, in which case a mid-forehead brow lift through a deep brow rhytid may be more appropriate.

Endoscopically assisted brow lifts may be useful for small amounts of brow ptosis and are therefore not satisfactory in older individuals with significant ptosis. In contrast to the direct methods involving skin excision, endoscopic brow lift suspends the periosteum in an elevated position until adherence by healing is obtained. Elevation of both brows and the complete frontal region appears necessary to address the hyperfunction observed in the unparalysed side, producing the best symmetry. An alternative is to weaken the contralateral normal frontalis muscle by frontal nerve denervation with or without frontalis muscle resection or chemodenervation with Botox. Preservation of the supratrochlear and supraorbital nerves is also achieved by direct visualization endoscopically and incisions are smaller with less sensory disturbance and less alopecia.

Management of the eye

The goal is to achieve complete eye closure, thereby providing corneal protection, with minimal ptosis in the open position. In principle, the upper eyelid needs to be lowered (unopposed action of levator palpebrae superioris) and the lower eyelid needs to be elevated. It is useful to separate the eye into static and dynamic options for the upper and lower lid.

Upper lid options

Lid loading was first described over 50 years ago and is well tolerated and highly efficacious. Gold and platinum have been the most widely used materials for implantation because of their high density and excellent side-effect profile.²⁰ The amount of weight required for complete closure is frequently too large, and a large weight is more likely to detach and erode through the

skin. Test weights attached to the upper eyelid with double-sided tape are used preoperatively to determine the lightest weight that will bring the eyelid within 2–4 mm of the lower lid. The most commonly selected weights are 1.0 g and 1.2 g, though standard sizes range from 0.6 to 1.8 g. For the best results, they should be placed at least 4 mm above the lid margin (to decrease visibility). Care must be taken to avoid damage to the levator insertion during the dissection for placement to avoid ptosis. Patients are advised that eyelid closure is a slow rather than a rapid blink and that they must practise holding the closure. Complications include a visible lump (capsule formation), ulceration and/or extrusion, migration of the weight and irritation of the cornea. More recently, a flexible platinum chain has been described as an alternative to rigid gold weights, with multiple links allowing flexibility to adapt to the shape of the globe. Platinum has a better biocompatibility profile and a higher density compared to gold and can thus be made into a smaller implant with improved cosmesis.

An alternative to lid loading is levator lengthening.²¹ The patient should be examined standing up and asked to close their eyes maximally; the width of sclera still exposed is the amount the levator needs to be lengthened and is typically approximately 5 mm. Through a standard blepharoplasty incision, the levator is exposed and separated from the tarsal plate and medial and lateral horns. A separate incision is made, hidden in behind the hairline, to harvest a deep temporal fascia graft. The size is measured and an additional 2 mm is harvested to allow for suture fixation to the levator and tarsal plate. The graft is inset and eye closure can be assessed once the patient is awake.

Lower lid options

There are fewer options to correct the lower eyelid in isolation as a consequence of the upper lid primarily controlling eye closure. In terms of static support for the lower lid, the use of autologous conchal cartilage grafts can be an effective procedure to improve the function and appearance of the atonic lower eyelid.

A fascial or palmaris longus tendon sling can be used to provide support the lower lid. The sling is fixed at the medial canthal ligament and supraorbital margin laterally. Proper placement of the tendon 1–2 mm below the lid margin is crucial as low placement will exacerbate an ectropion and high placement may result in an entropion.

Combined options

A tarsorrhaphy results in support of the lower eyelid and decreases the amount of corneal exposure by lowering the upper lid. McLaughlin's lateral tarsorrhaphy involves resection of the posterior lamellar of the upper lid (tarsal plate and conjunctiva) as well as an identical area of anterior lamellar of the lower lid (skin and muscle).²² The two denuded areas are overlapped and both tarsal plates are sutured. It is indicated in patients with concomitant senile ectropion but may result in the appearance of a smaller eye and difficulty when looking laterally. If this fails to achieve the desired result, then a fascial or palmaris longus

tendon sling is used as well. Canthoplasties are rarely performed as they tend to stretch over time in patients with facial paralysis.

The palpebral spring implant is a wire shaped by the surgeon in the form of an open safety pin. The lower arm is attached to the lid margin and the upper arm to the superior orbital rim. When the eye is opened by contraction of the levator muscle, the spring is compressed. When the levator is relaxed, the spring expands and forces the eyelid to a closed position. It has an advantage over upper lid weighting in that it will function equally well in the upright or supine position, but the results depend on the experience of the operator and the spring may loosen or fracture with time.²⁰

The transfer of a strip of temporalis muscle was first described by Gilles to provide a dynamic closure of the eyelid using autologous tissue.²³ A 1.5 cm strip of temporalis muscle is detached superiorly, turned anteriorly, and extended with two strips of tendon or fascia, passed through the upper and lower eyelids, and fastened to the medial canthal ligament. Alternatively, a static sling can be placed in the lower lid as previously described and a dynamic temporalis transfer applied to the upper lid as this eyelid requires more movement. The temporalis muscle transfer is activated by closing the jaw and therefore frequent biting throughout the day results in frequent corneal lubrication. It does result in a bulge over the lateral orbital margin and a slit-like appearance to the eye and is technically demanding to perform, but it can provide forceful and full eyelid closure, especially if the tension of the transferred muscle has been set correctly.

In order to restore the blink reflex, FFMT must be considered. This should ideally be performed as part of a two-stage reanimation process where two cross-facial nerve grafts are harvested, one being attached to a functioning buccal branch, the other to a zygomatic branch of the contralateral side. At the second stage, a free platysma flap may be raised with its neurovascular pedicle, tunnelled through the upper and lower lids and attached to the medial canthal ligament medially and temporal fascia laterally. The neurovascular pedicle is then typically joined to the cross-facial nerve graft (CFNG) from the functioning zygomatic branch and the superficial temporal vessels. This provides the patient with true spontaneous eye closure and restoration of the blink reflex.

A combination of lid loading, lateral tarsorrhaphies and lower eyelid slings are the most frequently carried out procedures on the eyelids in facial paralysis patients. In spite of this, treatment of epiphora is frequently unsatisfactory and may persist as a result of reduced inhibition on the lacrimal gland.

Management of the mid- and lower face

The surgical treatment of the mid- and lower face can be divided into static and dynamic options. In elderly patients, or in cases where dynamic options are unavailable, the mainstay of treatment is with autologous grafts or synthetic materials. The use of synthetic grafts offers the benefit of no donor site morbidity at

the risk of increased infection and extrusion of the material. Many examples of autologous grafts exist, ranging from palmaris longus to the Achilles tendon, however tensor fascia lata yields good to excellent results.²⁴ The graft can be easily harvested with two parallel incisions over the lateral thigh and provides sufficient graft length and breadth in comparison to others. The graft is split into three distal slips, one being inserted at the midline of the upper lip, one just beyond the midline in the lower lip and the last being inserted at the modiolus. Overtensioning of the graft is required in order to compensate for stretching over time. Due to the breadth of the graft, excellent support of the cheek is achieved which improves function and aesthetic appearance of the mid-face. An adjunct static procedure, much akin to a lateral canthopexy in the eye, is to close the angle of the mouth. Although this reduces the aperture of the mouth, it helps to lift the lower lip to improve symmetry at rest and improve symptoms.

Dynamic reanimation of the mid-face can be achieved with regional muscle transfers using the temporalis muscle, the masseter muscle or with a free microvascular (functional) muscle transfer.²⁵ A masseter muscle transfer results in a hollow at the angle of the mandible from where the muscle has been removed. In 1934, Gillies folded the temporal muscle over the zygoma to the lip subcutaneously, resulting in significant muscle bulging over the zygoma and a residual hollow in the temporal fossa. McLaughlin developed an intraoral approach to the coronoid process, removing part of the coronoid. The coronoid is then attached to fascia lata slings secured to the modiolus around orbicularis oris, allowing for a dynamic result using the whole of the temporalis.²⁶ Morrison's widely used modification is an extraoral approach to the temporalis tendon and placement of fascia lata grafts. In 1997, Labbé modified this technique further by carrying out an osteotomy of the zygomatic arch,²⁷ detachment at the coronoid process for insertion to the lips and temporalis muscle repositioning/lengthening by detaching the posterior third, resulting in a 'temporalis slide'. This procedure avoids contour problems and the routing provides good excursion but patients have to undergo intense physical therapy to relearn function. This is useful in patients for whom FFMTs are less effective and more unreliable. Using local muscle transfers requires the brain to retrain in order to achieve truly spontaneous results; with age, cortical plasticity diminishes and whether it is possible to achieve such a result remains to be seen.

Lower lip deformity is due to lack of innervation of the depressor labii inferioris by the marginal mandibular nerve. This is more evident during speech when the paralysed side remains elevated and the non-paralysed side moves inferiorly. Non-surgical management includes chemodenervation with Botox of the non-paralysed depressor labii inferioris to improve symmetry. Surgical options include selective myectomy of the non-paralysed depressor labii inferioris through the buccal surface of the lip, sectioning of the marginal branch of the contralateral facial nerve or transfer of the anterior belly of digastric muscle on the paralysed side. The anterior belly of

Figure 23.3 Unilateral facial reanimation. (a) Preoperative photograph showing a right sided facial paralysis. (b) Postoperative photograph after facial reanimation using a pectoralis minor free functional muscle transfer.

digastric is supplied by the mylohyoid branch of the mandibular division of the trigeminal nerve, and is spared in facial paralysis. The muscle can be divided at the tendinous junction separating the two bellies and then transferred over the chin (Conley's transfer).²⁸ It is secured to orbicularis oris at the lower lip and acts to recreate the downwards dynamic motion of the mouth and help symmetrize the position of the mouth, particularly during speech or eating. In more complex congenital facial hypoplastic conditions such as first arch syndrome, or following extensive surgery in the digastric triangle, where the anterior belly of digastric may be absent or damaged, an alternative option is a free EDB transfer or a mini-hypoglossal nerve transfer.

FFMT was popularized by Harii and continues to be the gold standard of treatment for facial paralysis. It allows for a true spontaneous smile to be restored. The use of FFMT in adults has evolved over the years and different treatment modalities are available depending on age groups. When considering muscle choice, the clinician must take into account muscle bulk, pedicle length and the size of the nerve. If a bulky muscle, such as latissimus dorsi, is used then adequate trimming of the muscle must be performed prior to inset. Pedicle length is vital if a one-stage procedure is to be considered.

For patients under the age of 20 years, a two-stage reconstruction is still advocated. Below this age, the ability of a nerve to regenerate along a CFNG is predictable and therefore favourable and the same two-stage procedure as described for the paediatric group is performed (Figure 23.3) utilizing gracilis or pectoralis minor for the FFMT.

In patients between 20 and 40 years, a one-stage procedure may be performed. In this case, a distal branch of the contralateral functioning buccal branch is used to neurotize the FFMT, and is approached via a small incision over the nasolabial fold. A muscle is chosen with a long pedicle length (typically latissimus dorsi) as the recipient nerve has to be tunnelled from one side of the face to the other and coapted

to the donor buccal branch directly. The advantage this has over a two-stage procedure is that the nerve only has to cross over one neurotomy in contrast to two in CFNGs and allows for a sufficient number of axons to reinnervate the muscle. This one-stage procedure also allows for a spontaneous symmetrical smile as it is powered by the contralateral facial nerve.

For patients between the ages of 40 and 60 years, similarly a one-stage procedure is advocated, however the donor nerve of choice is an ipsilateral branch of the masseteric nerve. The masseteric nerve is chosen due to the increased axonal counts, which are sufficient to power a FFMT and compensates for the increased age. In patients over 60 years, FFMT is not suggested as the results become increasingly unpredictable and fewer patients achieve good results.

In situations that require a planned segmental excision of the facial nerve, such as facial nerve involvement with a parotid carcinoma, a nerve graft may be used. A sural nerve can be coapted to the proximal and distal stumps of the divided nerve and a good recovery can be achieved. It is important to note that this is unaffected by radiotherapy treatment, which is a frequent treatment modality in this patient group.^{29,30}

Frequently a facial palsy patient may require multiple operations. This is in part due to the changes of an ageing face but also to improve cosmesis. Static slings may stretch over time and require tightening or an FFMT may require revision due to the patient not being happy with the bulkiness. Although 80% of FFMT obtain either a good or excellent result, 20% gain no benefit and warrant another surgical option.¹⁵

Conclusion

The essential primary strategy when approaching the management of facial paralysis is to assess the patient in detail and to form a tailored plan for each individual. In general, early referral

to a facial reanimation service is recommended, particularly in the paediatric group. A facial reanimation unit should be in a specialized centre which can cater for paediatric services and should also be able to deliver all the options available to a patient.

Currently, there is no standardized outcome measurement for facial palsy surgery, although the surgical community is working towards this. Photographic and video assessment by a specialized panel of judges appears to be the most widely used and transferable.¹⁵ More detailed methods of measuring vectors of movement in the face are incredibly time consuming and almost impossible to perform on small children.

The ultimate aim of facial reanimation is to address all the branches of the facial nerve. The goal is to restore facial symmetry, allow for spontaneous movement and preserve function; this will serve to protect the cornea and improve speech and oral continence, allowing for the normal expression of emotion.

CHAPTER 24

Head and neck malignancy: staging and neck dissections

Andrew N. Morritt, Marlene S. See and Navid Jallali

Department of Plastic Surgery, Charing Cross Hospital, London, UK

Introduction

The majority of malignant tumours of the head and neck region are squamous cell carcinomas (HNSCCs) arising from the mucosa of the upper aerodigestive tract. HNSCC is the fifth most common neoplasm worldwide, with greater than half a million new cases occurring per year globally.¹ The major tumour sites include the oral cavity, the nasopharynx, the oropharynx, the hypopharynx, the larynx, the nose and the paranasal sinuses. Tumours occur most commonly in the oral cavity, which collectively accounts for 60% of all oral cancer cases in the UK (2010).²

Oral cancer is the 15th most common cancer in the UK, accounting for 2% of new cases (6539 new cases in 2010) and its incidence has increased since the 1970s.² It is more common in males than females (incidence: 2 : 1, male : female), and with increasing age, with approximately 50% of cases occurring in patients aged between 45 and 64 years and 44% of cases occurring in those over 65 years of age.²

The increasing incidence of oral cancer in the UK is probably due to changes in the prevalence of major risk factors for oral cancer, such as heavy alcohol consumption, smoking and infection with the human papilloma virus (HPV).² Cumulative changes in DNA caused by the synergistic effects of cigarette smoking and alcohol are thought to underlie the majority of oral cancer cases. This may explain the variations in geographical incidence of oral cancer within the UK, with the highest incidence rates occurring in Scotland, Northern Ireland and the North of England.³

Assessment of the patient with head and neck cancer

The assessment of the patient with head and neck cancer involves a multidisciplinary team (MDT) approach, comprising history and clinical examination, radiological and histopathological evaluation. The clinical information is collated and

discussed at a head and neck MDT meeting to formulate a management plan. In our unit, the core MDT comprises a head and neck surgeon, a plastic and reconstructive surgeon, an oncologist, a radiologist, a pathologist, a clinical nurse specialist, a dietician, a prosthetist and a speech therapist. Important points considered in the decision-making process for treatment include: patient age, tumour factors (site and extent), comorbidity, social circumstances and the patient's wishes.

History

The history can provide useful information regarding the primary tumour, any secondary metastases, and the patient's general health/fitness for surgery. Age is an important consideration as elderly patients generally have more comorbidity, less functional reserve and may be more difficult to successfully rehabilitate for speech and swallowing than younger ones. We do not, however, have a cut-off age for microvascular transfer and reconstruction and would not exclude a patient based on age.

Tumour symptoms are frequently related to the anatomical location of the neoplasia. Rapidly progressive symptoms suggest aggressive disease in contrast to slow progression, which suggests less aggressive disease. The past medical history is important as comorbidities can increase the risks of surgery and of general anaesthesia and ultimately affect prognosis. Tumours developing in the immunocompromised generally have a poor prognosis. The social history is of particular importance in planning physical and psychological rehabilitation following treatment. Furthermore, the history should include an assessment of the risk factors for development of head and neck cancer such as alcohol and tobacco use.

Clinical examination

A general examination of cardiovascular, respiratory and abdominal systems to assess the patient's fitness for surgery and also to detect signs of metastasis is performed. This is combined with an examination of the primary tumour and of the cervical lymph node groups. The primary tumour is inspected with a good light source (e.g. headlight) and palpated to determine:

position, borders and functional effect. Palpation of the tongue may reveal tumour that is not obvious on inspection alone. Fibreoptic endoscopy is useful for the examination of nasal cavity, nasopharynx and the larynx. The piriform fossa can be exposed by asking the patient to exhale against a closed mouth, which causes the cheeks to blow outwards.⁴

The cervical lymph node groups are examined by standing behind the patient, with the patient's neck slightly flexed to relax the strap muscles. Palpation of all cervical lymph node groups is performed in a systematic manner to ascertain the position, size, number of enlarged nodes and fixation of lymph nodes to adjacent anatomical structures or skin. Fine needle aspiration cytology (FNAC) is the initial investigation of choice for patients with cervical lymphadenopathy. The diagnostic accuracy is very high and there are no reports of seeding of head and neck tumours following FNAC.⁴ The adequacy of FNAC is improved if performed under ultrasound guidance.

The clinical assessment should also include an assessment of nutritional status as many of these patients are prone to malnutrition due to difficulties with eating and swallowing caused by the tumour, and also because they are often heavy smokers and drinkers. Malnutrition can compromise wound healing and increase susceptibility to infection and preoperative feeding may be required to optimize these patients for surgery. In patients who are likely to require a long postoperative rehabilitation before swallowing, a radiologically inserted gastrostomy (RIG) tube is organized. Presurgical dental assessment is also vital in this group of patients. Many have high levels of dental neglect and periodontal disease and may need dental extractions at the time of ablative surgery, particularly if postoperative radiotherapy is likely. Some patients will also benefit from psychological assessment and counselling.

Haematological tests including full blood count, urea and electrolytes, liver function tests, clotting studies and a group and save are routinely performed. Many patients with head and neck cancer have synchronous tumours (e.g. carcinoma of the bronchus) and so chest X-ray or chest CT scan are routine before treatment. Other tests such as thyroid function tests, electrocardiograms, echocardiograms and respiratory function tests are performed when clinically indicated. Anaesthetic review is frequently sought to establish patient fitness for general anaesthesia.

Radiological examination

Radiological examination is a vital part of the assessment of the patient with head and neck cancer. It provides information about the site and extent of primary tumour, neck node involvement (number of nodes, size, position), distant metastases and synchronous primary tumours, which is ultimately used in staging. CT scans are fast and provide excellent bony detail but expose the patient to relatively large doses of ionizing radiation. CT scans are the staging investigation of choice in our unit. MRI can also be used but scan times are significantly longer than those for CT. MRI may therefore not be suitable for all patients (many patients with head and neck cancer have difficulty with

breathing, swallowing, lying flat and keeping still). Positron emission tomography (PET) has a role in evaluating the patient with an unknown primary and will detect the primary in approximately one third of cases.⁴ Other imaging modalities have specific indications: barium swallow is useful in assessment of some hypopharyngeal tumours and some tumours of the cervical oesophagus; an orthopantomogram can show tumour invasion of the mandible and dental disease, and may be useful in planning surgery for tumours of the oral cavity and oropharynx.

Endoscopy

The majority of patients with head and neck cancer undergo rigid endoscopy under general anaesthesia to establish the position and extent of the primary tumour and to obtain tissue biopsies. Radiological imaging should be performed before biopsy in order to avoid the effect of upstaging from oedema caused by biopsy. Biopsies should be taken from the viable part of the tumour (i.e. not from the centre (may be necrotic), and not from the edge (may only show dysplasia)).

Panendoscopy or triple endoscopy (laryngoscopy combined with oesophagoscopy and bronchoscopy) is performed to exclude a synchronous primary tumour in the upper aerodigestive tract although its routine use is controversial.⁴ Arguments for routine panendoscopy include: it is quick, has low morbidity and is easily performed at the time of endoscopy for the primary site tumour. Arguments against routine panendoscopy include: it creates extra risks and expense, and detection rates are similar to those with symptom-directed investigations combined with routine chest radiography. Panendoscopy is therefore only recommended for symptomatic patients, patients with primary tumours at high risk of a synchronous primary tumour (e.g. oropharynx), and patients who have suspicious abnormalities on radiological studies. Panendoscopy also has a role in the investigation of the patient with an unknown primary tumour where high-risk sites (ipsilateral tonsil, nasopharynx, ipsilateral tongue base, piriform fossa) are biopsied.⁴

Staging

The tumour, node, metastasis (TNM) staging system developed by the American Joint Committee on Cancer (AJCC) in 2002 is the most widely used system to establish disease stage and prognosis, and also to direct management. The clinical information used in TNM staging comes from the physical examination, radiographic, intraoperative and pathologic findings. The TNM system is composed of three categories: T – the characteristics of the primary tumour (may be based on size, location or both); N – the degree of regional lymph node involvement; and M – the absence or presence of distant metastases. The given TNM status translates to the disease stage (I–IV). Early-stage disease is denoted as stage I or II disease, and advanced-stage disease as stage III or IV disease. Of note, any metastatic neck disease will classify the disease as advanced (except in selected nasopharynx or thyroid tumours).^{5,6}

Although the definitions for Tx, T0 and Tis are the same for all primary tumours of the head and neck region, the definitions for T1–4 vary according to anatomical site of primary tumour (see Tables 24.2, 24.3, 24.7, 24.9 and 24.10). Tx indicates that the primary tumour cannot be assessed; T0 indicates that there is no evidence of primary tumour and Tis is defined as carcinoma *in situ*.

Anatomical sites

The upper aerodigestive tract (UADT) begins where the skin meets the mucosa at the nasal vestibule and the vermilion borders of the lips and continues to the junction of the cricoid cartilage where the hypopharynx meets the cervical oesophagus. This chapter focuses on sites with the greatest incidence of pathology and on subsites with specific reconstructive challenges. Tumours of the thyroid gland and salivary glands are beyond the scope of this chapter but interested readers are referred to other comprehensive texts for detailed discussion.⁷

Table 24.1 Primary tumour site locations of the oral cavity

Lip	Skin – vermilion junction to oral mucosa
Buccal mucosa	Mucosal lining extending from pterygomandibular raphe anteriorly
Alveolar ridge	Gingival mucosa anterior to retromolar trigone
Retromolar trigone	Mucosa behind the last mandibular molar tooth extending superiorly to the maxillary tuberosity; overlies the anterior aspect of the ascending ramus of the mandible
Hard palate	Bounded by the superior alveolar ridge and the junction of the soft palate
Floor of mouth	Bounded by the inferior alveolar ridges and the tongue
Anterior tongue (2/3)	Extends anteriorly from the circumvallate papillae and bounded by floor of mouth

Source: Saadeh and Delacure, 2007.⁸ Reproduced with permission of Lippincott, Williams and Wilkins.

Oral cavity^{5,8}

The anterior border is the junction of the skin and vermilion border of the lip. The posterior border is formed by the junction of the hard and soft palates superiorly, the circumvallate papillae inferiorly, and the anterior tonsillar pillars laterally. Primary tumour site locations within the oral cavity are summarized in Table 24.1. T-staging for the oral cavity is summarized in Table 24.2.

Nasopharynx^{5,8}

The nasopharynx includes the vault, the lateral walls, the posterior walls, and the superior surface of the soft palate. Table 24.3 summarizes the T-staging for tumours of the nasopharynx.

Oropharynx^{5,8}

The oropharynx begins where the oral cavity ends at the junction of the hard and soft palates superiorly and the circumvallate papillae inferiorly. It extends from the level of the soft palate superiorly (which separates it from the nasopharynx) to the level of the hyoid inferiorly (where the hypopharynx begins). Table 24.4 defines primary tumour site locations within the oropharynx. Table 24.2 summarizes the T-staging for the oropharynx.

Hypopharynx and cervical oesophagus^{5,8}

The hypopharynx extends from the hyoid bone superiorly, where it is contiguous with the oropharynx, and extends inferiorly to the cricopharyngeus muscle, where it meets the cervical oesophagus. Table 24.5 defines the primary tumour site locations of the hypopharynx and cervical oesophagus. Table 24.2 summarizes the T-staging for tumours of the oropharynx.

Larynx^{5,8}

The larynx is bordered by the oropharynx superiorly, the trachea inferiorly, and the hypopharynx laterally and posteriorly. The larynx is subdivided by the vocal cords into the supraglottic,

Table 24.2 T-staging for primary tumours of oral cavity, oropharynx and hypopharynx^{5,6}

	Oral cavity	Oropharynx	Hypopharynx
T1	<2 cm	<2 cm	One subsite and is <2 cm
T2	2–4 cm	2–4 cm	More than one subsite or 2–4 cm with NO fixation of hemilarynx
T3	>4 cm	>4 cm	>4 cm or fixation of hemilarynx
T4a	Lip – Tumour invades through cortical bone, inferior alveolar nerve, floor of mouth, or skin of face (i.e. chin or nose)	Invades the larynx, deep/extrinsic muscle of the tongue, medial pterygoid, hard palate, or mandible	Invades thyroid/cricoid/hyoid/oesophagus/central compartment soft tissues
Moderately advanced local disease	Tongue – Extrinsic muscles, fixed tongue or mandible invaded		
T4b	Invades masticator space, pterygoid plates or skull base or encases the internal carotid artery	Tumour invades the lateral pterygoid muscle, pterygoid plates, lateral nasopharynx, or skull base or encases the carotid artery	Invades prevertebral fascia, mediastinum or encases carotid artery
Very advanced local disease	[Note: Superficial erosion alone of bone/tooth socket by gingival primary is not sufficient to classify a tumour as T4]

Table 24.3 T-staging for tumours of the nasopharynx^{5,6}

T1	Tumour confined to the nasopharynx, or extends to the oropharynx and/or nasal cavity, without parapharyngeal extension
T2	Tumour extends into the parapharyngeal space
T3	Tumour involves bony structures and/or paranasal sinuses
T4	Tumour with intracranial extension and/or involvement of cranial nerves, infratemporal fossa, hypopharynx, orbit, or masticator space

Table 24.4 Primary site locations within the oropharynx

Soft palate	Extends from the hard palate junction to the uvula posteriorly and anterior tonsillar pillars laterally
Tonsil	Bounded by the tonsillar pillars
Lateral pharyngeal wall	Extends from posterior tonsillar pillar to posterior pharyngeal wall
Posterior pharyngeal wall	Bounded by the lateral pharyngeal walls and extending from the level of the hard palate superiorly and hyoid bone inferiorly
Posterior tongue (1/3; base of tongue)	From circumvallate papillae to epiglottis

Source: Shah, 2003.⁷ Reproduced with permission of Elsevier.

Table 24.5 Primary tumour site locations within the hypopharynx and cervical oesophagus

Postcricoid region	Extends from the arytenoids superiorly to the cricoids cartilage inferiorly
Posterior pharyngeal wall	Anterior to retropharyngeal space and extends from the level of the epiglottis to the level of the cricoids cartilage
Piriform sinus	Pyramidal in shape with base superiorly and apex inferiorly. Extends from the oropharynx superiorly to the laryngeal ventricles inferiorly. Medial border is the lateral cricoids cartilage. Lateral border is the medial thyroid cartilage. The posterior border is bounded by both the lateral and posterior pharyngeal walls
Cervical oesophagus	Extends from the cricoids level to the sternal notch

glottic and subglottic subsites. Table 24.6 defines the primary tumour site locations of the larynx. Table 24.7 summarizes the T-staging for tumours of the larynx.

Nasal cavity and paranasal sinuses

Primary tumour sites within the nasal cavity and paranasal sinuses are summarized in Table 24.8. Table 24.9 summarizes T-staging for tumours of the maxillary sinus. Table 24.10 summarizes T-staging for tumours of the nasal cavity and ethmoid sinus.

Table 24.6 Primary tumour site locations within the larynx

Supraglottis	Epiglottis, arytenoids, aryepiglottic folds, and false cords
Glottis	True vocal cords, the anterior and posterior commissures
Subglottis	Below the glottis extending to the inferior margin of the cricoid cartilage

Source: Saadeh and Delacure, 2007.⁸ Reproduced with permission of Lippincott, Williams and Wilkins.

Table 24.7 T-staging for the supraglottis, glottis and subglottis respectively^{5,6}

	Supraglottis	Glottis	Subglottis
T1	One subsite of the supraglottis, normal vocal cord movement	T1a one vocal cord involved, with normal mobility T1b both cords involved with normal mobility	Limited to subglottis
T2	Invades mucosa of other subsite of supraglottis but no laryngeal fixation	Invades into sub or supraglottis or impaired mobility of the cords	Extends to vocal cords
T3	Limited to larynx with vocal cord fixation or invasion of post cricoid area, periglottic spaces or thyroid cartilage	Limited to larynx with cord fixation or invasion of paraglottic space or inner cortex thyroid cartilage	Limited to larynx with vocal cord fixation
T4a	Invades through thyroid cartilage or beyond larynx	Invades through thyroid cartilage or beyond larynx	Invades cricoid or thyroid cartilage or beyond larynx
T4b	Invades prevertebral space or mediastinum or encases carotid artery	Invades prevertebral space or mediastinum or encases carotid artery	Invades prevertebral space or mediastinum or encases carotid artery

T4a, moderately advanced local disease; T4b, very advanced local disease.

Neck staging under the TNM staging system for head and neck tumours^{5,6,8}

Table 24.11 summarizes the neck staging system for primary tumours of the head and neck region (excluding nasopharynx). Table 24.12 summarizes the neck staging system for primary tumours of the nasopharynx.

Distant metastasis under the TNM staging system for head and neck tumours^{5,6,8}

Table 24.13 summarizes distant metastasis under the TNM staging system.

TNM stage grouping

Tables 24.14 and 24.15 summarize the TNM stage groupings for tumours of the head and neck region.

Table 24.8 Primary tumour site locations within the nasal cavity and paranasal sinuses⁵

Nasal cavity	Extends superiorly from the walls of the ethmoid sinus anteriorly and the sphenoid sinus posteriorly down to the hard palate anteriorly and nasopharynx posteriorly. Lateral margins are the medial walls of the maxillary sinus and the nasal cavity is bisected sagittally by the septum
Maxillary sinus	Bounded superiorly by the orbital floor, inferiorly by the hard palate, posteriorly by the pterygoid plates and pterygopalatine fossa, and laterally by the pterygoid muscles and mandibular ramus
Frontal sinus	Above and along the anterior aspect of the ethmoid sinus
Ethmoid sinus	Between medial orbits, superior to the nasal cavity
Sphenoid sinus	Skull base, posterior to the ethmoid sinus

Source: Saadeh and Delacure, 2007.⁸ Reproduced with permission of Lippincott, Williams and Wilkins.

Table 24.9 T-staging for primary tumours of the maxillary sinus^{5,6}

T1	Tumour is limited to the maxillary sinus mucosa, with no erosion or destruction of bone
T2	Tumour is causing bone erosion or destruction, including extension into the hard palate and/or middle nasal meatus, except extension to the posterior wall of the maxillary sinus and pterygoid plates
T3	Tumour invades any of the following: bone of the posterior wall of the maxillary sinus, subcutaneous tissues, floor, or medial wall of the orbit, pterygoid fossa, or ethmoid sinuses
T4a	Tumour invades anterior orbital contents, skin of cheek, pterygoid plates, infratemporal fossa, cribriform plate, sphenoid or frontal sinuses
T4b	Tumour invades any of the following: orbital apex, dura, brain, middle cranial fossa, cranial nerves other than maxillary division of trigeminal nerve (V2), nasopharynx, or clivus

T4a, moderately advanced local disease; T4b, very advanced local disease.

Table 24.10 T-staging for primary tumours of the nasal cavity and ethmoid sinus⁵

T1	Tumour is confined to the ethmoid sinus with or without bone erosion
T2	Tumour invades two subsites in a single region or extends to involve an adjacent region within the nasoethmoidal complex, with or without bony invasion
T3	Tumour extends to invade the medial wall or floor of the orbit, maxillary sinus, palate, or cribriform plate
T4a	Tumour invades any of the following: anterior orbital contents, skin of nose or cheek, minimal extension to anterior cranial fossa, pterygoid plates, sphenoid or frontal sinuses
T4b	Tumour invades any of the following: orbital apex, dura, brain, middle cranial fossa, cranial nerves other than (V2), nasopharynx or clivus

T4a, moderately advanced local disease; T4b, very advanced local disease.

Table 24.11 Neck staging for primary tumours of the head and neck region (excluding nasopharynx)^{5,6}

Nx	Regional lymph nodes cannot be assessed
N0	There is no regional nodes metastasis
N1	Single ipsilateral lymph node metastasis ≤ 3 cm in greatest dimension
N2a	Single ipsilateral lymph node metastasis ≥ 3 cm but < 6 cm in greatest dimension
N2b	Multiple ipsilateral lymph node metastases, all < 6 cm in greatest dimension
N2c	Bilateral or contralateral lymph node metastases, all < 6 cm in greatest dimension
N3	Lymph node metastasis > 6 cm in greatest dimension

U, L, A designation of 'U' or 'L' may be given in addition to indicate the level of metastasis above the lower border of the cricoid cartilage (U) or below the lower border of the cricoid cartilage (L).

Table 24.12 Neck staging for primary tumours of the nasopharynx^{5,6}

Nx	Regional lymph nodes cannot be assessed
N0	There is no regional lymph node metastasis
N1	Unilateral lymph node metastasis(es), ≤ 6 cm in greatest dimension, above the supraclavicular fossa
N2	Bilateral lymph node metastasis(es), ≤ 6 cm in greatest dimension, above the supraclavicular fossa
N3	Lymph node metastasis/es is ≥ 6 cm and/or to the supraclavicular fossa
N3a	Tumour is ≥ 6 cm in dimension
N3b	Tumour extends to the supraclavicular fossa

Table 24.13 Distant metastasis under the TNM staging system^{5,6}

M0	No distant metastasis
M1	Distant metastasis

Neck dissection

The lymph node levels of the neck

The Memorial Sloan Kettering level system, which divides the lymph nodes of the neck into six distinct groups (Figure 24.1) is the widely accepted system for describing the location of lymph node disease in the neck. Levels I, II and V are subdivided into sublevels (Figure 24.2).⁹ Table 24.16 summarizes the six lymph node groups and six sublevels. Table 24.17 summarizes the anatomical boundaries of the levels and sublevels of lymph nodes in the neck.

Neck dissection

'Neck dissection' is the general term used to describe the surgical removal of the fibrofatty contents of the neck, for the treatment or assessment of the cervical lymph nodes. Neck dissections are classified as comprehensive (radical, modified radical, extended radical) or selective, based on the nodal levels dissected and the structures preserved (Table 24.18). Radical neck dissection (RND) was historically the standard procedure for the management of both clinically positive and occult metastases in the cervical lymph

Table 24.14 Stage grouping for primary tumours of the oral cavity, oropharynx, larynx, and hypopharynx^{5,6}

	T	N	M
Stage 0	Tis	N0	M0
Stage I	T1	N0	M0
Stage II	T2	N0	M0
Stage III	T3	N0	M0
	T0, T1, T2 or T3	N1	M0
Stage Iva	T4a	N0 or N1	M0
	T1, T2 or T3	N2	M0
Stage Ivb	T4b	Any N	M0
	Any T	N3	M0
Stage Ivc	Any T	Any N	M1

Stage IVa, moderately advanced local/regional disease; stage IVb, very advanced local/regional disease; stage IVc, distant metastatic disease.

Table 24.15 Stage grouping for primary tumours of the nasopharynx^{5,6}

	T	N	M
Stage 0	Tis	N0	M0

	T4	N1	M0
	T4	N2	M0
Stage IVB	Any T	N3	M0
Stage IVC	Any T	Any N	M1

nodes. However, over the last two decades there has been a shift towards more conservative surgical procedures as neck dissection with conservation of non-lymphatic structures gives equivalent oncologic outcomes with improved functional results.^{10,11}

Radical neck dissection

RND was first described by Crile in 1906 and involves unilateral removal of lymph node levels I–V, the spinal accessory nerve (SAN), the internal jugular vein (IJV) and the sternocleidomas-toid muscle (SCM). RND is now reserved for patients with advanced neck disease, recurrent disease after chemoradiation or gross extracapsular spread to the SAN, IJV and SCM.

Modified radical neck dissection

Modified radical neck dissection (MRND) comprises removal of lymph node levels I–V with preservation of one or more of the non-lymphatic structures which are normally resected in RND (i.e. the SAN, IJV and SCM). The structure or structures preserved should be indicated in the name of the procedure (e.g. MRND

Figure 24.1 The six levels of the neck. Source: Cummings *Otolaryngology-Head and Neck Surgery*, 5e, Paul Flint et al., 2010. Reproduced with permission of Elsevier.

Figure 24.2 The six sublevels of the neck. Source: Cummings *Otolaryngology-Head and Neck Surgery*, 5e, Paul Flint et al., 2010. Reproduced with permission of Elsevier.

with preservation of accessory nerve and IJV), however the following nomenclature has gained widespread acceptance;

- MRND I – Preservation of SAN
- MRND II – Preservation of SAN, SCM
- MRND III – Preservation of SAN, SCM and IJV

Extended neck dissection

Extended neck dissection (END) is the combination of RND with removal of additional structures such as additional lymph node groups or non-lymphatic structures (e.g. carotid artery, cranial nerves, muscles or the parotid gland) that are not routinely removed in RND.

Selective neck dissection

Selective neck dissection (SND) describes a neck dissection where there is preservation of one or more lymph node levels that are routinely removed in RND (Table 24.16). SND has been developed based on the observation that cervical metastases in previously untreated patients proceed in a predictable fashion depending on the site of the primary tumour.¹² Hence, the lymph node groups most likely at risk of involvement can be removed while those at low risk of involvement may be safely preserved.^{10,11} For oral cavity cancers, the lymph nodes at greatest risk are located in levels I–III. The lymph nodes at greatest risk for oropharyngeal, hypopharyngeal and laryngeal cancers are located in levels II–IV, and for thyroid cancer are in level VI.

Indications for neck dissection

As previously mentioned, there is a trend away from performing RND towards MRND/SND. MRND is indicated for clinically palpable metastatic neck disease but conversion to RND sometimes becomes necessary upon gross involvement of the SAN, IJV, SCM. RND may also be indicated in recurrent disease. Bilateral MRND is indicated when there is contralateral lymph node involvement.

SND is generally performed in patients who have N0 disease but who have a high probability of occult disease and in all cases that require microsurgical reconstruction to gain access to the vessels. SND may also sometimes be performed for N1 disease in levels I or II. SND (I–III) is performed for oral cavity cancer. Some authorities recommend SND (I–IV) for tongue cancer as level IV is also at risk.⁹ Bilateral SND (I–III) is indicated in patients who have tumours of the floor of mouth/anterior tongue where lymph nodes on both sides of the neck are at risk. SND (II–IV) is performed for oropharyngeal, hypopharyngeal and laryngeal cancers while SND (VI) is performed for thyroid cancer. Posterolateral neck dissection (= SND II–V + postauricular and suboccipital nodes) is performed most commonly to remove nodal disease from cutaneous malignancies of the posterior scalp and neck. END is performed in patients with

Table 24.16 The lymph node levels and sublevels of the neck⁹

Level (nodal group)	Anatomy	Likely primary site
Level I	Submental (sublevel 1A): nodal tissue superior to the hyoid bone and between the anterior bellies of the digastric muscles. Submandibular (sublevel 1B): nodal tissue between the mandibular border, the anterior bellies of the digastric muscles and the stylohyoid muscle, includes the submandibular gland	Floor of mouth, anterior oral tongue, anterior mandibular alveolar ridge, lower lip Submandibular gland, oral cavity, anterior nasal cavity, midfacial soft tissues
Level II Upper jugular	Nodal tissue along the upper third of the internal jugular vein extending from the skull base to the inferior border of the hyoid bone. Anterior border is lateral border of stylohyoid muscle, posterior border is posterior border of sternocleidomastoid muscle Sublevel IIA: tissue anterior to the spinal accessory nerve Sublevel IIB: tissue posterior to the spinal accessory nerve	Oral/nasal cavity, nasopharynx, oropharynx, hypopharynx, larynx, parotid gland
Level III Middle jugular	Nodal tissue along the middle third of the internal jugular vein extending from the inferior border of the hyoid bone to the inferior border of the cricoid cartilage. Anterior border is lateral border of sternohyoid muscle, posterior border is posterior border of sternocleidomastoid muscle	Oral cavity, nasopharynx, oropharynx, hypopharynx, larynx
Level IV Lower jugular	Nodal tissue along the lower third of the internal jugular vein extending from the inferior border of the cricoid cartilage to the clavicle. Anterior border is lateral border of sternohyoid muscle, posterior border is posterior border of sternocleidomastoid muscle	Hypopharynx, cervical oesophagus, larynx, thyroid gland
Level V Posterior triangle	Nodal tissue along the lower half of the spinal accessory nerve and the transverse cervical artery. Triangle is defined by the posterior border of the sternocleidomastoid muscle, the anterior border of the trapezius muscle, and the clavicle. Also includes the supraclavicular lymph nodes Sublevel VA: tissue above the horizontal plane marking the inferior border of the anterior cricoid arch Sublevel VB: tissue below the horizontal plane marking the inferior border of the anterior cricoid arch	Oropharynx, nasopharynx, posterior scalp and neck
Level VI Anterior compartment	Nodal tissues delimited by the hyoid bone superiorly, sternal notch inferiorly, and common carotid arteries laterally. Includes the pretracheal and paratracheal nodes, precricoid (Delphian node), and the perithyroidal nodes	Thyroid, glottic/subglottic larynx, piriform sinus apex, cervical oesophagus

Table 24.17 Anatomical structures defining the levels and sublevels of the neck⁹

Level (nodal group)	Boundary
Level IA	Superior: symphysis of mandible Inferior: body of hyoid Anterior (medial): anterior belly of contralateral digastric muscle Posterior (lateral): anterior belly of ipsilateral digastric muscle
Level IB	Superior: body of mandible Inferior: posterior belly of digastric muscle Anterior (medial): anterior belly of digastric muscle Posterior (lateral): stylohyoid muscle
Level IIA	Superior: skull base Inferior: horizontal plane defined by the inferior body of the hyoid bone Anterior (medial): stylohyoid muscle Posterior (lateral): vertical plane defined by the spinal accessory nerve
Level IIB	Superior: skull base Inferior: horizontal plane defined by the inferior body of the hyoid bone Anterior (medial): vertical plane defined by the spinal accessory nerve Posterior (lateral): lateral border of sternocleidomastoid muscle
Level III	Superior: horizontal plane defined by inferior body of hyoid Inferior: horizontal plane defined by inferior border of cricoid cartilage Anterior (medial): lateral border of sternohyoid muscle Posterior (lateral): lateral border of the sternocleidomastoid or sensory branches of cervical plexus
Level IV	Superior: horizontal plane defined by inferior border of cricoid cartilage Inferior: clavicle Anterior (medial): lateral border of sternohyoid muscle Posterior (lateral): lateral border of the sternocleidomastoid or sensory branches of cervical plexus
Level VA	Superior: apex of the convergence of the sternocleidomastoid and trapezius muscles Inferior: horizontal plane defined by the lower border of the cricoid cartilage Anterior (medial): posterior border of the sternocleidomastoid muscle or sensory branches of cervical plexus Posterior (lateral): anterior border of the trapezius muscle
Level VB	Superior: horizontal plane defined by the lower border of the cricoid cartilage Inferior: clavicle Anterior (medial): posterior border of the sternocleidomastoid muscle or sensory branches of cervical plexus Posterior (lateral): anterior border of the trapezius muscle
Level VI	Superior: hyoid bone Inferior: suprasternal Anterior (medial): common carotid artery Posterior (lateral): common carotid artery

Table 24.18 Types of neck dissection

Type	Levels dissected	Preserved structures	Primary tumour
RND	I–V	None	
SND (I–III)	I–III	XI+STM+IJV	Oral cavity
SND (II–IV)	II–IV	XI+STM+IJV	Oro/hypopharynx, larynx
SND (I–IV)	I–IV	XI+STM+IJV	Tongue
SND (VI)	VI	XI+STM+IJV	Thyroid
SND (II–V + occipital and postauricular nodes) (Posterolateral)	II–V + occipital and postauricular nodes	XI+STM+IJV	Posterior scalp and neck

N+ necks who would otherwise be candidates for RND/MRND when there is evidence of invasion into other surrounding structures (e.g. carotid artery).

Complications of neck dissection

The complications of neck dissection can broadly be classified into: intraoperative complications (e.g. bleeding, air embolus,

pneumothorax, nerve injury); complications in the early postoperative phase (e.g. skin flap necrosis, carotid artery blowout, chyle leak); and those that occur in the late postoperative phase (e.g. scar contracture, neuroma, shoulder pain syndrome, cellulitis and facial/cerebral oedema).

Chyle leak is rare and typically presents with drainage of milky fluid, although the fluid may be clear if the patient is

fasting or on a fat-free diet. The medical management of chyle leak includes leaving drains on continuous suction, application of a pressure dressing and bed rest. Dietician input is important and an elemental feed supplemented with medium-chain triglycerides may be given enterally. Total parenteral nutrition is used in refractory cases. Surgical intervention has been advocated for greater than 500 mL drainage per day persisting after one week of medical treatment, persistent low-output drainage occurring over a prolonged period, and if complications occur.¹³

Synchronous bilateral radical neck dissections may result in the development of facial oedema, cerebral oedema, or both. The oedema, which is more common in patients who have had previous radiation to the head and neck, is thought to be due to inadequate venous drainage and usually improves as collateral circulation develops. Preserving at least one external jugular vein in patients undergoing bilateral radical neck dissection can reduce postoperative facial oedema.

Indications for radiotherapy

External beam radiotherapy alone or in conjunction with chemotherapy has a well-established role in the treatment of head and neck cancer as definitive therapy or as an adjuvant to primary surgical treatment.⁸ Radiotherapy is also used in metastatic disease to relieve symptoms and to achieve local control. Adjuvant radiotherapy should ideally begin within 4–6 weeks following primary surgical resection and neck dissection, unless postoperative complications significantly delay wound healing. Delaying adjuvant therapy has been shown to significantly reduce locoregional control. Of recent note, inhibition of the epidermal growth factor receptor (EGFR) with the monoclonal antibody cetuximab has been shown to improve both disease-free survival and overall survival when combined with radiotherapy for stage 3/4 disease.¹⁴

In the presence of limited disease, the factors that influence the selection of treatment modality (surgery versus external beam radiotherapy versus brachytherapy) include primary tumour site, age, comorbidity, occupation, preference and quality of life following treatment. Surgery is the treatment of choice for early-stage oral cavity and paranasal sinus tumours. Surgery is preferred to radiotherapy in the oral cavity due to the risk of osteoradionecrosis from radiotherapy and because oral cavity SCCs may be less sensitive to radiotherapy than oropharyngeal or laryngeal cancers. Positive surgical margins, multiple involved lymph nodes, and/or extracapsular tumour spread may indicate postoperative radiotherapy ($\pm$ chemotherapy) to reduce local recurrence.⁸ In oropharyngeal, hypopharyngeal and laryngeal cancers, primary radiotherapy is generally preferred, as surgery is associated with greater levels of functional impairment and reduced quality of life.¹⁵ The treatment of laryngeal cancers varies widely, and for early-stage lesions, radiotherapy or transoral endoscopic excision are the most common treatment

options.⁸ The treatment of more advanced laryngeal tumours is controversial. Although total laryngectomy has historically been considered the gold standard for treating advanced laryngeal cancers, chemoradiotherapy has been shown to be quite effective in achieving local regional control, survival and voice preservation.⁸

CHAPTER 25

Oral tongue reconstruction

Stuart Archibald, Michael Gupta and Achilleas Thoma

Division of Otolaryngology-Head and Neck Surgery and Division of Plastic Surgery, Department of Surgery, McMaster University, Hamilton, Canada

The oral tongue: anatomic defect and functional deficit-guided reconstruction

The oral tongue, which occupies most of the oral cavity, has diverse and important functions, and is also a common site for intraoral malignancy.^{1,2} Most oral tongue cancers require surgical treatment, with reconstruction according to underlying principles. Given that resections and reconstructions of the oral tongue can have wide-ranging functional consequences, it is best that a team approach with the ablative surgeon, the reconstructive surgeon and early input from the speech and language and swallowing therapists be developed.³ Because functional restoration is the main goal of reconstruction, in this chapter we present the principles that guide the selection of a reconstructive option to achieve this objective.

Normal and postresection altered anatomy and physiology

The anatomy and physiology of the oral cavity are complex. This overview concentrates on the oral tongue anatomy and physiology relevant to speech and swallowing, both in the normal person and in the patient after oral (mobile) tongue cancer resection and reconstruction.

The motor nerve to the tongue (hypoglossal, XII) is under voluntary control. It gives branches to the extrinsic tongue muscles and then ramifies to supply the intrinsic tongue muscles, supplying each side separately. The intrinsic tongue muscles (superior longitudinal, transverse, and inferior longitudinal and vertical), which interdigitate with the hyoglossus muscle, provide the oral tongue mobility, the change in shape, tissue volume and the intraoral position of the tongue, all so necessary for the coordinated oral preparatory and then transport phases of swallowing.⁴⁻⁷ The intrinsic muscles are also essential for speech. For instance, for the vowel sounds, the vertical height of the tongue and the shape of its dorsal and lateral aspects must be varied for

each vowel. For the consonants, the anterior/tip of tongue is required for the anterior 'stops' (e.g. 't', 'd', where the tongue must touch the anterior teeth or hard palate), the posterior oral tongue is required in tongue-palate contact for the posterior 'stops' (e.g. 'k', 'g'), the entire oral tongue is needed to change the airflow to a funnel as in 'laterals' (e.g. 'l') or to a constricted pattern as in 'fricatives' (e.g. 's', 'sh', 'th').⁸ All of these motor activities require a high degree of fine motor coordination, and depend on intact sensation to function normally.

The extrinsic muscles with the genioglossus, and chondroglossus attaching anteriorly and working with the geniohyoid, mylohyoid muscle and anterior digastric muscles, and the styloglossus attaching posteriorly and working with the palatoglossus and posterior digastric muscle,⁹ function to give a stable but moveable foundation for the tongue to work against in the oral preparatory and transport phases of swallowing. Many of these same muscles work to elevate the laryngo-hyoid complex in the pharyngeal phase of swallowing.

Thus a deep resection of the oral tongue can affect both oral stages of swallowing as well as the pharyngeal phase.

The main requirements of oral tongue function for speech and swallowing are:

- motility of appropriate portions for the task required;
- adequate tissue bulk plus ability to selectively alter that volume;
- positioning of the tongue.

Because different regions of the oral tongue predominate in different tongue actions, with the anterior, middle and posterior thirds variably involved, we consider the regions separately in the resections and reconstructions to follow, realizing, however, that many resections, although centred on one region, usually involve more than one region on the affected side, and may extend to the opposite side. Defects which extend to several regions take on the functional deficits of those regions also. In the simplest case, a functional deficit of a tip defect may affect the anterior 'stops' in speech, may limit the ability to move food within the mouth in the oral preparatory stage in swallowing

and, if tethered anteriorly, will impair the oral transport stage, compounding that with a tendency to drool. Each region of the oral tongue can be similarly profiled.

Classification systems of anatomic defects

No widely accepted classification system of defects has been developed. The proposals vary considerably in their categories and detail.^{10–15} The difficulties relate to the complexity of the oral cavity and its functions, the three-dimensional nature of these resections, with deeper resections, particularly those involving deep muscles and nerves, giving very different functional changes for the same surface area, and the ability of individual patients to adapt differently to what appears to be the same defect. Generally the extent of surface resected broadly correlates with the deficit of function.¹⁶ A suitable classification system must find the balance between complexity and simplicity so that only essential information is collected, must be easy to use, must be reproducible, must be reportable in a meaningful easily understood way, and must achieve the following objectives:

- accurately define the surface resected of the tongue, floor of mouth, alveolar process and mandible, buccal region and oropharynx;
- accurately define the deeper structures resected as to bone, muscle, nerve(s); and
- accurately determine the tissue volume resected.

A classification system is not an end in itself. For applicability, it must be linked to the reconstructive option(s) and procedural manoeuvres used, and then scored as to specific outcomes, for instance in speech and swallowing. Until such a coherent system is developed, only partial and approximate answers can be given to: What is the precise defect? What are the functional problems from it? What reconstruction manoeuvres and tissue give the optimal result? How does this 'optimal' result remain deficient? What deficiencies attend alternative reconstruction choices? How are the outcomes to be measured in a standardized fashion^{10,17} and ranked? The answers to these questions will only be found in well-designed multicentre studies.¹⁷

Goals of surgical reconstruction

The overall goal is to preserve and/or restore optimum speech, dental hygiene capability and eating functions, including those of the oral preparatory (mastication and bolus formation) and oral transport stages of swallowing.¹⁸ Often, the defect in a specific case can only be estimated preoperatively. The ideal assessment for a particular patient occurs after the resection, when the surgeon can estimate the functional deficits based on what has been resected and what remains, and then draw a defect template. Then, the various reconstruction approaches can be considered. For this reason, decisions regarding reconstructions

are best done after the defect has been fully created, especially for the less-common or complex defects. In practice, for the common scenarios and to facilitate the logistical arrangements required for a two-team surgical approach, a preoperative decision is made which limits the reconstructive options based on what the most likely defect and its associated functional deficit will be, and only modifications to one of the preselected options are performed.

The persistent factors affecting speech intelligibility are age, tumour localization, resection volume, method of reconstruction and administration of postoperative radiation therapy.^{19, 20} Loss of tongue mobility, loss of tissue bulk, loss of control of appropriate intraoral position of the tongue and lack of propulsive power are the greatest hindrances to proper swallowing.²¹ Therefore, the surgeon will strive to:

- retain as much viable, sensate, and motile native tissue as possible without violating sound oncologic principles;
- reconstruct the tongue epithelial surface primarily if possible, especially if postoperative radiation therapy is contemplated;
- maintain the separation between the oral cavity and neck (this is particularly relevant when the resection includes the adjacent floor of mouth and an ipsilateral neck dissection);
- preserve extrinsic tongue muscles and pharyngeal muscles as much as possible in the resection (where one or more of these has to be sacrificed, manoeuvres such as laryngeal suspension, cricopharyngeus myotomy and reconstruction of the oral diaphragm between the mandibular mylohyoid lines should be considered);
- preserve some tongue tip, or create a 'neo-tip,' possibly with a flap;
- preserve tongue mobility by avoiding tethering of the remaining tongue tissue;
- minimize the intraoral insensate area (consider sensory neurotization of the flap; unresected contralateral tongue, even if small as in some subtotal oral glossectomies, should be sensate and motile if at all possible);
- restore volume of lost tissue (anteriorly this will prevent depressed excavations which allow secretions and food to collect and pool; laterally–posteriorly this promotes the movement of an intraoral food bolus posteriorly and to the opposite functioning side and promotes the acquisition of good articulation);
- replace and stabilize resected mandible with vascularized bone secured by internal fixation, and preserve dentition according to dental goals (if osseointegration is planned, then the bone needs to be robust and of suitable vertical height; loss of vertical height anteriorly changes facial proportions).

Surgical options

The first decision that the surgeon must make after resecting oral tongue cancer is whether to close the defect or part of it primarily, or whether to use a flap for some or all of the reconstruction. In the pre-flap era, primary closure, closure by secondary

intention, or use of a tongue flap were all employed in the closure of sizeable defects. This resulted in significant impairment of swallowing and speech, even with small defects.⁶ The development of flaps opened up the possibilities of improved oral function in speech and swallowing,^{13, 22–26} and better cosmesis. Speech and swallowing may vary as to the advantage that each gains from flap reconstruction.^{27–29}

Decision making in surgery is based on the defect and resultant functional deficits being reconstructed, the flaps available, the technical facilities available, and the surgical team's experience. The final result is additionally strongly affected by the patient's age and motivation, the additional treatment given (for example radiation therapy) and the rehabilitation team's expertise.

Primary closure

Primary closure is usually possible when the defect allows the remaining dorsal tongue tissue to be coapted to remaining ventral tongue tissue. Loss of tongue volume of up to one third of the oral tongue in many cases will not give serious permanent swallowing problems.^{20, 30} Tongue loss can be overcome to a certain extent by compensatory mechanisms. When the resection involves ventral tongue to the extent that primary closure would result in tethering of the dorsal tongue tissue to the floor of the mouth mucosa, as when less than 1 cm of mucosa remains following a mid-third oral tongue resection between the resection margin and the gingiva, then an alternative method should be used.¹⁶

Healing by secondary intention

When a defect, in whole or in part, cannot be entirely closed primarily (or when a primarily closed defect opens in the postoperative period), healing by secondary intention follows. Such healing takes time, delaying subsequent treatment such as radiation therapy. During the healing, the patient has more local discomfort and must work diligently at oral hygiene. In some cases there is a greater chance of neck contamination. Once healing is complete, these sites can be harder to assess for early local recurrence. Nevertheless, in the appropriate patient this approach is well tolerated and the best option, and is frequently employed following laser resections.²⁰ Generally, swallowing is less impaired than is articulation with primary closure or healing by secondary intention.

Skin grafting, either by full thickness or split thickness

This is seldom the ideal method of reconstruction. Most small defects do not require this approach, and most larger defects are better managed otherwise, as restoration of bulk becomes increasingly important. Skin grafts may be applied to small defects which have a good recipient bed of tongue muscle, and where restoration of tissue volume is not necessary. In these cases the graft should be larger than the maximum dimensions of the defect to allow for some graft shrinkage.¹⁶ The use of a bolster dressing to maximize the chances of graft 'take' may be poorly tolerated

and some patients may require an otherwise-unnecessary tracheostomy. Furthermore, many such grafts simply function initially as biological dressings for a wound which then heals by secondary intention when the graft is lost, following which the grafted area progressively shrinks. 'Quilting' of the graft may avoid some of the above problems, but the shrinkage of the grafted site with a tendency for tethering remains a drawback. However, in a select few (usually edentulous) patients who are poor candidates for a flap option, and who have a shallow, uniform vascularized resection bed, this can be a useful technique. Mucosal grafts, which are of necessity small, do not offer any advantage over primary closure or skin grafts.

Intraoral local flaps

The attraction of these flaps is the ability to replace lost mucosa with mucosa. The limitations are the area that can be resurfaced, the lack of bulk, and with buccal donor sites, potential for contracture whether closed primarily or by a skin graft.

The first candidate for this approach is the tongue flap. Despite replacing 'like' with 'like,' it is almost never justifiable, because the surgery takes tissue from the remaining tongue with unnecessary additional functional compromise, and there are now many better reconstruction options. The second possibility is the facial artery myo-mucosal (FAMM) flap,^{31, 32} which is anterior to Stensen's duct and is supplied by the facial artery and based either superiorly or inferiorly.³³ The third option is the buccinator myomucosal island flap.^{34–36} Such flaps may be posteriorly based on the buccal artery from the internal maxillary artery, or anteriorly based from branches of the facial artery,^{37, 38} giving a good range of reach. In edentulous non-irradiated patients with a modest-sized defect where bulk is not a critical issue, this flap can be an excellent choice. The donor site morbidity is low if the flap is carefully planned and oriented.

Pedicled extraoral locoregional flaps

These options are useful when a free flap is not available, or not required, or not likely to be well tolerated by the patient.

The submental artery (SMA) flap was first described by Martin *et al.*³⁹ and has become a preferred option in some centres.⁴⁰ These flaps are robust pedicled flaps of good thickness and surface area which will reach all areas of the ipsilateral tongue, floor of mouth and oropharynx. Raising the flap can be moderately difficult, and the venous drainage is not always reliable. Flap viability in larger series is over 90%. However, their elevation requires dissection where nodal metastases from the oral tongue are prone to occur. Therefore, this flap must be used with caution, and only in cases where the neck, being easy to examine clinically and radiologically, is staged as N0. Some patients who are poor candidates for an alternative flap, and for whom postoperative radiation therapy is planned, are well served by this flap.

Infra-hyoid myocutaneous flaps⁴¹ have seen limited use in oral reconstruction as yet. In the presence of a tracheostomy

there is an increased risk of wound infection. The flap is fairly robust and mostly hairless, and is adequate to reconstruct modest-sized defects. It may be susceptible to venous insufficiency unless a modified approach is taken,⁴² and also requires careful dissection along the superior thyroid artery to preserve its blood supply. Raising this flap does not carry the same risk of violating the principles of a sound oncologic dissection as may be the case in the SMA flap, but caution is advised nevertheless.

The supraclavicular artery island flap (SCAIF) is a recently developed flap based on the supraclavicular branch of the transverse cervical artery, supplying the fasciocutaneous island over the shoulder tip and extending down over the mid-lateral deltoid muscle.⁴² It will reach the oral cavity for floor of mouth and tongue reconstructions. It offers pliable hairless skin of good size. Experience is still limited with it, thus its place still has to be determined. If its early promise is sustained, it may well displace some of the more demanding, time-consuming and expensive free flap options.

Pectoralis major myocutaneous (PMC) flap, first described by Ariyan⁴³ is presently more used in the salvage situation. It is easy to raise and fairly reliable. The main problems with it is that it suffers from a bulky pedicle relative to the usual tunnel between the neck and the oral cavity beneath an intact mandible, it creates an unsightly bulge in the neck, and its skin paddle is from the random part of the flap, all of which challenge viability. The skin does not regain useful sensation.⁴⁴ The flap recipient site will sag with time creating intraoral pooling, although technical refinements can minimize this problem.⁴⁵ There is significant donor site morbidity with this flap, with a cumulative effect on shoulder dysfunction in cases where there has been a neck dissection around the spinal accessory nerve.

The delto-pectoral flap, described by Bakamjian⁴⁶ became the first widely used axial pattern flap for major head and neck reconstruction. It is very occasionally useful in the intraoral reconstruction-salvage situation, but otherwise is mainly of historical significance. These flaps are easy to raise, and are usually reliable provided the dissection of the proximal pedicle does not endanger the supplying internal mammary artery perforators by coming too close to the midline, and the flap is made long enough to avoid tension when reaching the resection site. This gives the desired distal part of the flap a random arterial supply which increases risk of necrosis. The skin does not regain sensation unless reinnervated.⁴⁷ If the flap survives, it is often too thick when a thin flap is desired, or alternatively too thin to provide needed bulk. The pedicle is subject to compression as it enters the oral cavity, and conventionally it must be divided in a second stage. The reliability is lower than that of the PMC flap.

Naso-labial flaps, whether interpolated or not, offer a small area of tissue with limited reach, and find little application for tongue reconstruction.

Platysmal flaps are generally unreliable, thin and difficult to orientate for tongue reconstruction. As a result, they have found little use in these situations.

Free flaps

Free flaps are the most reliable reconstructive method, with over 95% viability common. They provide a non-mucosal desquamating surface of skin or skin graft which means that 'like' has not been replaced with 'like'. However, the skin surface becomes thinner in the intraoral environment. Although free flaps using jejunal wall to give a mucosal surface have been tried, a major abdominal procedure is not warranted except in the very rare case of incapacitating oral dryness. Free flaps can be neurotized, or allowed to reinnervate spontaneously from peripheral or resection bed nerve endings,⁴⁸ with some evidence that function of the reconstructed tongue is improved by surgical reinnervation.⁴⁹ A single free flap is used most often, sometimes with a multilobed skin island,⁵⁰ but multiple free flaps in extensive and complex defects can be employed, or a free flap can be combined with a non-free flap option. Free flaps most commonly used in oral tongue reconstruction are discussed below.

Radial forearm free flap

This venerable free flap⁵¹ is the commonest one used in intraoral reconstruction, and large series of cases have been reported.^{52, 53} It may be raised as a fasciocutaneous, or osteocutaneous flap. The skin paddle can be specifically designed for the defect²⁶ or a bilobed or multilobe design which allows the oral tongue and floor of mouth portions to be somewhat separate.¹⁶ A proximal fascial component (the 'beavertail' modification⁵⁴) can provide a random part which can then be shaped to provide bulk. The radial forearm free flap (RFFF) can be raised with two or more discreet skin paddles. The appeal of this flap in oral tongue defect reconstructions is its reliability, its long vascular pedicle which opens up a range of possible recipient vessels without the need for vein grafts, and most importantly its thin pliable versatile skin paddle of adequate size which makes this the best flap to prevent tongue tethering. Good speech and swallowing are reported after using this flap.⁵⁵ Modifications to the skin paddle giving extra bulk will facilitate tongue-palate contact and secondarily aid glosso-pharyngeal closure. The flap can be neurotized using the lateral antebrachial cutaneous nerve,⁵⁶⁻⁵⁸ but if not, some spontaneous return of sensation occurs over time.^{43, 59} Although there is no unequivocal evidence that neurotization itself gives better oral function than spontaneous reinnervation,²¹ perhaps only hastening the recovery of protective sensation, it can be recommended as a simple step in the procedure, which can only be of benefit or of no use, and cannot be harmful to the patient. When harvested as an osteocutaneous flap, the bone is unsubstantial, fragile and poorly tolerant of osteotomies, thus best limited to situations where a straight bony reconstruction which will not be expected to provide osseointegrated implants is acceptable. The radius bone at the donor site has a significant risk of distal fracture, and prophylactic plating in high-risk situations should be considered. The flap donor site which is usually closed with a split-thickness skin graft may be conspicuous. The graft may not always 'take', especially over exposed tendons even though the

paratenon layer is preserved. In selected cases, the flap donor site can be closed using a proximal advancement flap. Intraoral hair growth on the skin island can be a nuisance, but becomes less problematic over time, and is eliminated by postoperative radiation. Despite its limitations, this flap remains a frequent choice for oral tongue defect reconstructions where thin pliable skin to maintain tongue motility is the primary objective, and bulk is a secondary issue.

Anterolateral thigh flap

The anterolateral thigh flap (ALT), more recently popularized,^{60–62} provides a large skin paddle, although the skin is less pliable than the RFFF. It is reliable, provided that the perforating vessels are carefully identified and preserved, and it can have a moderately long pedicle. It can be reinnervated.⁶³ Harvesting can take place during the ablation procedure, adding to the efficiency of the operation. Donor site morbidity is minimal. The major limitations with it are the thickness of the subcutaneous tissue, which if too thick make it unsuitable for some oral tongue reconstructions. The flap can be raised in a suprafascial plane which makes it thinner overall. A variation, where a portion is thinned *in situ* prior to division of the pedicle to preserve the subdermal vascular plexus, has been used to give a thin part of the flap for the floor of mouth or to give tissue laterally over the defect from a marginal mandibular resection. The risk of flap failure is slightly higher than that of the RFFF as the perforator vessels are small, and the pedicle is more susceptible to compression in the tunnel between the oral cavity and the recipient neck vessels.

Lateral arm free flap

The lateral arm free flap (LAFF), first described by Song *et al.*,⁶⁴ has become popular for tongue reconstruction where more bulk is required.^{12,65} Being fasciocutaneous, it does not atrophy to any extent. The skin provided is more pliable in most patients than that of the anterior thigh region and it can be innervated using the posterior cutaneous nerve of the arm, which may enhance tongue function.⁶⁶ The donor site can be closed primarily. It can be modified by a proximal forearm extension,⁶⁷ and it has been used as a musculocutaneous flap, harvesting some triceps muscle with the skin flap.⁶⁶ The major limitation of this flap is its short pedicle with small-diameter vessels, making its revascularization more technically demanding, and consequently its failure rate somewhat higher. It is awkward to harvest this flap while the ablation is in process.

Brachioradialis musculocutaneous flap

The ability to offer innervated muscle and a reliable skin paddle which can be innervated make this a possible, although rarely selected free flap.⁶⁸ It is more challenging to raise, and imposes a small donor site penalty with about a 20% reduction in the strength of elbow flexion. The harvested brachioradialis muscle in some muscular patients can give considerable bulk which is mostly retained or restored with successful neurotization. The pedicle of this flap is shorter than the RFFF. Probably the most

telling strike against this flap and others involving reinnervated muscle, however, is the lack of high-quality evidence as to how significant neurotization of the transferred muscle is in improving reconstructed tongue function.

Rectus abdominis musculocutaneous free flap

Although this flap is used in head and neck reconstructions mainly for skull base, mid-face, and scalp defects, it can be used to reconstruct major (total or subtotal) defects of the oral tongue,⁶⁹ or more commonly of the combined mobile and posterior tongue. It is a reliable flap, whose main advantage is the provision of soft tissue bulk, which aids in the tongue–palate and/or tongue–pharyngeal wall apposition during the late oral and the pharyngeal phases of swallowing. It can be reinnervated, but spontaneous reinnervation from axons from remaining tongue tissue also occurs.⁷⁰ Of course a unidirectional muscle cannot duplicate the complexity of the extrinsic–intrinsic muscles, but some contraction may help with tongue–palate contact and bolus propulsion. It can have a long pedicle. It can be raised without the rectus muscle component, and only the anterior rectus sheath with the overlying fasciocutaneous island sustained by a single perforator. In this configuration, the anterior rectus sheath can be secured laterally in the oral defect to provide support for the remaining intraoral flap tissue.

Defects and reconstruction selection

Often, in oral tongue and related oral defects, the best results come from the cumulative benefit of several reconstructive manoeuvres. Nevertheless, these defects often carry significant functional disability in speech and swallowing which even the best reconstruction cannot correct. It is important that patients and the treatment team are well aware of this from the outset.

The following categorization of oral tongue regions is adopted because defects of each region cause different functional changes,⁷¹ which influence the reconstruction options.

Anterior third

Tip only

A midline tip defect is best closed primarily with remaining sensate tissue from each side. Although the tongue is thereby shortened, this is not usually a problem with eating, and gives minor articulation changes. Where the defect is unilateral, the remaining tip is best closed to itself, as this give a sensate although narrow tip. No significant eating difficulties result, and the articulation change is small, although it may be slightly more than in the primarily closed central defect.

Anterior third of oral tongue only

The remaining tip is ideally closed, giving a sensate residual tongue tip, and the more posterior portion of the defect can be closed primarily if no tethering would occur, or otherwise with a local intraoral flap or skin graft in selected cases. A free flap is

not usually required unless more than the anterior third of the unilateral oral tongue is resected.

Anterior third of oral tongue with floor of mouth, mandible preserved

The lesions requiring this type of resection may be primaries in the floor of mouth which spread to the tongue, or primaries in the tongue which spread to the anterior floor of mouth. In either case, the resection may be hindered by intact anterior mandibular teeth, and if so, the teeth should be extracted to guarantee adequacy of resection and/or to facilitate reconstruction. The main problems resulting from non-flap reconstructions, such as primary or secondary closures and skin grafts, are the significant tethering of the tongue with serious speech impairment and problems with the oral phase of swallowing, and pooling of saliva and fluids which predisposes to drooling. However, some of these cases can be adequately managed using an anteriorly based buccinator myomucosal island flap. The remainder are often best reconstructed using an RFFF.

Some lesions are deceptively small on the oral surface, but have a larger and deeply infiltrative extension. This situation can usually be anticipated by adequate clinical and imaging examination preoperatively, and confirmed by careful bimanual examination under anaesthesia before the resection commences. If the resection is deep into the the genioglossus/geniohyoid/hyoglossus muscles, sometimes including the mylohyoid and anterior digastric muscle, the surgeon must be aware of two additional dangers. The first is the possibility of extension to the inner table of the mentum, as this requires bone resection. Second, even if no bone needs to be resected, the additional problem created by the deep anterior muscle resection changes the nature of the defect and consequently the reconstruction. Restoration of the hyoid to mandible complex should be provided, and the deeper defect will need to be filled by some bulk, for which the RFFF may still be the best option, possibly using one of the modifications to the skin/fascial island.

Anterior third of oral tongue with floor of mouth and anterior mandible

It makes a difference if the anterior mandible resection is marginal or segmental. In the former case, restoration of the bony height is a lower priority than in the latter. Sensation to the lower lip should be preserved, if necessary by releasing the inferior alveolar nerve on at least one side from its bony canal. If the decision is to restore lost bony height, then this may be achieved to a degree by an onlay of bone from either the RFFF, which still gives the pliable skin for soft tissue reconstruction, or the fibula free flap (FFF), whose skin and soft tissue is less reliable and thicker. If the decision is made not to correct for the lost bone height after a marginal resection and only to reconstruct the soft tissue, then an RFFF can be used, and even in some cases (for example, in the salvage situation after flap failure) a split-thickness skin graft provided that the tongue tip is not tethered. When a full segmental resection is done, then the bone must be

reconstructed, and the flap usually used is the FFF, on which the bone can be 'double-barrelled' to give better bone height. Alternatives include a free iliac crest osteocutaneous flap.

Mid-third of oral tongue

This part of the oral tongue provides important tongue mobility and bulk in bolus propulsion, as well as central depression in bolus formation. The reconstruction cannot provide all of these functions. Bulk for bolus transport takes precedence over central depression in bolus preparation, and tissue volume restoration gives better articulation results than does leaving a central third of oral tongue volume deficit. The adjacent floor of mouth covers the lingual nerve as it courses to the anterior third of the oral tongue. When the nerve is segmentally resected, no restoration of sensation to the anterior third of the tongue is usually provided, as the unilateral sensory deficit is well tolerated.

Middle third of oral tongue only

The defects of the middle third of the oral tongue that can be closed primarily are those where the tongue mobility will not be compromised by that approach. As the medial resection approaches the midline furrow, increasing the vertical thickness of the tongue resected, there is greater tendency for tethering with primary closure, causing significant speech impairment. An RFFF will preserve mobility, but if more bulk is needed, either a modified RFFF or an LAFF will be useful. The ALT is usually too large unless adjacent portions of the oral tongue are also resected as in a true oral tongue hemi-glossectomy.⁷²

Mid-third oral tongue with floor of mouth

As the floor of mouth becomes part of the defect, then an RFFF or LAFF are useful options, or in some cases an SMA flap where there is no oncologic concern in the neck as noted above.

Mid-third oral tongue with floor of mouth and lateral mandible

If the mandible is segmentally resected, then bony replacement as part of the reconstruction is preferred, as the use of a reconstructive plate alone frequently results in eventual plate exposure. Since the defect is lateral, there may be no need for bony osteotomy. In that case, an osteocutaneous RFFF may be a good option especially if no dental implants are planned. Where the bony defect is more extensive, or where osteotomies are required, or when osseointegrated implants are planned, then an FFF is most commonly employed.

Posterior third of oral tongue

This portion of the tongue is required in propulsion of the oral bolus posteriorly, and in apposition against the palate superiorly and towards the pharyngeal wall posteriorly for both swallowing and speech. It works in concert with the extrinsic tongue muscles and the pharyngeal constrictors in a coordinated fashion. The lingual nerve is usually resected, and frequently also the hypoglossal nerve.

Posterior third oral tongue with/without lateral soft tissue

When the defect is of this part of the tongue only, in many cases it can be closed primarily or allowed to heal by secondary intention. When properly selected, the resultant narrowing of the entry into the oropharynx compensates for the reduction in tissue volume. Such isolated defects are fairly rare, as resections more commonly involve one or more neighbouring regions such as the adjacent oral tongue anteriorly, base of tongue posteriorly, the oropharynx superolaterally, or the mandible laterally, in which case a flap reconstruction should be performed to restore missing volume, retain mobility and restore mandible continuity (see below). Nerve grafting to bridge the lingual nerve gap is done if possible. The hypoglossal nerve is not reconstructed, but if the branch to the base of the tongue is saved then the pharyngeal phase of swallowing will be better.

Posterior third oral tongue and lateral soft tissue plus mandible

These defects are common, and involve sacrifice of the inferior alveolar nerve, the lingual nerve and usually a segment of the jaw, although a marginal resection is sometime possible, sparing the need for bony reconstruction. The best reconstructions involve nerve grafting for the inferior alveolar and lingual nerves, neurotization of the free flap skin from the proximal lingual stump, soft tissue replacement with fasciocutaneous component of the free flap and bone reconstruction as indicated. The commonest flap in these situations is the FFF, although if no bone is required, an LAFF or even an RFFF can be good options. The skin island should not reconstruct a large area of the base of tongue portion of an extended defect to avoid insensate skin being just above the larynx, a situation which favours aspiration; rather, the base of tongue part of the defect should be closed with sensate base of tongue remnant as is usually possible when the defect is less than half of the base of tongue.

Bilateral oral tongue

Bilateral oral tongue resections almost always proceed from anterior to posterior in terms of tissue resected; it is unusual to spare anterior portion(s) of the tongue and yet have bilateral oral tongue resected posteriorly. Preservation of motility and sensation to the unresected tongue is paramount for best results.

Anterior thirds of oral tongue

Reconstruction of the anterior tongue using a flap designed to give enough bulk for a 'tip', and with enough deep support of the reconstruction to preserve ability to contact anterior upper palate/teeth is the goal here. Sometimes, when the defect is asymmetrical, the side with the most tongue tissue remaining can be formed into a neo-tip of more use than a flap-constructed tip. The defect is limited when tongue alone is involved, in which case an RFFF will usually give enough bulk using one of the skin paddle modifications. Sometimes an LAFF is appropriate, although its short pedicle in this position can be

problematic. Neurotization of the flap is used. Where the defect includes the deep anterior extrinsic tongue muscles then a laryngeal suspension⁷³ and possible reconstruction of the oral platform between the mylohyoid lines will convert a deep defect to the more superficial one, allowing the same reconstruction as noted above with an RFFF or LAFF. Where bone is included in the resection, the reconstructive approach will follow that of 'Anterior third of oral tongue with floor of mouth and anterior mandible' above.

Anterior two-thirds of oral tongue/subtotal oral tongue glossectomy

In these defects, the vertical height and bulk of the reconstruction is even more important to maximize speech and swallowing, with mobility derived from the movement of the surviving tongue tissues and extrinsic tongue muscles. As above, where the deep tissues are resected, a laryngeal suspension and reconstruction of the oral platform are very helpful. The flap is usually either an ALT or rectus abdominis musculocutaneous free flap (RAMFF), but an RFFF or LAFF may be acceptable in some patients with adequate flap subcutaneous fat. The volume of soft tissue resected should be slightly overcorrected by the reconstruction. An FFF is commonly used if mandibular reconstruction is required. Various attempts have been proposed to make the reconstructed tongue assume the specific shape of the normal tongue.^{21, 27, 74, 75}

Total oral tongue glossectomy (may be termed a 'subtotal glossectomy')

Major defects such as this often include extrinsic muscles also, and are very difficult to reconstruct without obvious disability in eating and speech. Preservation of as much sensate and motile tongue base is essential to prevent chronic aspiration, and laryngeal suspension is used routinely. It is important to provide support for the intraoral reconstruction, whether by bone as with the iliac crest⁷⁶ or with soft tissue such as muscle.¹⁷ The commonest flaps employed are the ALT, the RAMFF or the gracilis muscle free flap,^{77, 78} taking care to overcorrect for lost volume. A strong case can be made for reinnervated muscle when such a flap is used. An occasional case where extrinsic tongue muscle loss is minimal can be reconstructed with an RFFF modified for volume augmentation, or with a brachioradialis musculocutaneous free flap. The reconstruction must ensure support for the intraoral tissue.

Conclusion

The oral tongue is difficult to reconstruct because of its sophisticated anatomy and coordinated movements in speech and swallowing. With attention to the defect created and the resultant functional deficits, the reconstructive surgeon should be able to select a reconstructive option which minimizes the impact of surgical treatment on these unfortunate patients.

Selected cases

Submental artery flap

This 55-year-old woman had a T2N0 squamous cell carcinoma (SCC) mainly of left middle third of oral tongue resected with posterior third, and coming within 1 cm of the midline, along with a selective ipsilateral neck dissection (Figure 25.1). Reconstruction was by a pedicled SMA flap. Postoperatively she received radiation therapy as there was a 7 mm node involved with cancer showing microscopic extracapsular spread (pN1). Now 7 years without recurrence, she has nearly normal speech and eats a full oral diet.

Lateral arm free flap

A 65-year-old man with a T3N1 SCC of the posterior third, and small amounts of adjacent middle third and base of tongue, underwent resection which spared the anterior third of oral tongue, crossing the midline furrow by 1 cm in the mid and posterior thirds (Figure 25.2). The base of tongue defect was closed primarily. An LAFF was used to reconstruct the soft tissue. He received postoperative radiation therapy. At eight months, he remains free of disease, and his speech is entirely intelligible with only some minor dysarthria. He eats a full diet.

Figure 25.2 Lateral arm free flap. (a) View of T3 SCC of right oral tongue. (b) Defect following resection of SCC of right oral tongue. (c) Lateral arm free flap inset into right tongue defect, providing good bulk.

Radial forearm flap

The resection on this 75-year-old man whose large T2N0 SCC straddled the middle and posterior thirds of the oral tongue included the posterior aspect of the anterior third and all of the middle and posterior thirds of the oral tongue, with a uniform fairly shallow resection (Figure 25.3). Reconstruction was by an RFFF. There was no radiation therapy. At over 4 years, he is free of disease, his speech is fully intelligible, and he eats a full diet.

Anterolateral thigh free flap, neurotized, with laryngeal suspension

A 55-year-old man, with a T4 left oral tongue cancer involving almost all of the left oral tongue, including the root of tongue, spreading across the floor of mouth to within 1.0 cm of the gingiva, crossing to within 1.5 cm of the right lateral tongue lateral border in the middle third, extending into the base of tongue and involving the lower half of the lateral oropharyngeal wall (Figure 25.4). Resection by a marginal mandibulectomy plus anterior

Figure 25.3 Radial forearm flap. (a) Shallow defect created by resection of T2 SCC right oral tongue. (b) Inset RFFF skin paddle into right tongue defect.

Figure 25.4 Anterolateral thigh free flap, neurotized, with laryngeal suspension. (a) Resected specimen of T4 tongue cancer. (b) Extensive involvement of almost all of the left oral tongue extending to left floor of mouth, with resection including marginal mandibulectomy. (c) Small remnant of contralateral oral tongue and root of left tongue remaining; a mandibulotomy to assist with exposure has been done.

Figure 25.5 Free fibula osteocutaneous free flap. Insufficient soft tissue from the skin paddle of a free osteo-cutaneous fibula flap has severely compromised this patient's speech, and rendered him feeding-tube dependent.

Figure 25.6 Radial forearm flap, with mesh to reconstruct oral diaphragm. The radial forearm fascio-cutaneous free flap has been supported by replacing the resected oral "diaphragm" with synthetic mesh, and the hyo-mandibular complex further restored by a laryngeal suspension, giving good speech and swallowing of pureed foods.

mandibulotomy, left only the anterior third, some root and extrinsic muscles, a lateral middle third margin and some posterior third and the base, all on the contralateral side. Reconstruction involved partial base of tongue primary closure, some primary closure of the residual contralateral tongue tip, and soft tissue replacement with a neurotized ALT flap. The reconstruction gave incomplete palato-glossal contact, with a prolonged oral transit stage, and abnormal oropharyngeal stage. He regained swallowing of fluids and some oral soft foods without on-going gastrostomy tube feeds, but his speech was markedly impaired. He had postoperative radiation therapy complicated by osteoradionecrosis requiring a second flap (FFF), and then developed local recurrence at 12 months. This proved highly responsive to three cycles of chemotherapy and he survived for the next 3 years.

Free fibula osteocutaneous free flap

This man shows a suboptimal reconstruction from 18 years previously using an osteocutaneous FFF after a subtotal oral glossectomy and mandibulectomy (Figure 25.5). The patient received postoperative radiation therapy. The soft tissue was inadequate and almost immobile, severely compromising his oral and pharyngeal phases of swallowing, and rendering his speech barely intelligible. He remains feeding-tube dependent. He has refused all offers of further reconstructions.

Radial forearm flap, with mesh to reconstruct oral diaphragm

This man, now 12 years post operative after a subtotal oral glossectomy and marginal mandibulectomy reconstructed with laryngeal suspension, restoration of the oral mandible 'diaphragm' with mesh to allow the RFFF to have adequate oral height, has intelligible speech and problem-free swallowing of fluids and pureed food (Figure 25.6). He has been fully employed since his treatment.

CHAPTER 26

Mandibular reconstruction

Christopher Glenn Wallace, Chung-Kan Tsao and Fu-Chan Wei

Department of Plastic and Reconstructive Surgery, Chang Gung Memorial Hospital, Chang Gung University and Medical College, Taipei, Taiwan

Introduction

The mandible and its attached musculature play an important role during many social interactions, including eating, drinking, talking and maintenance of oral continence. Aesthetically, its inferior margin defines the lower third of the face, its dimensions contribute to facial height, width and profile, and its dentition highlights a smile. A functionally asymmetric mandible can lead to long-term problems, including dental malocclusion, articulation difficulties, painful temporomandibular joint pathology, and unattractive static and dynamic facial disproportions. Accordingly, a suboptimal mandibular reconstruction can impact multifactorially on overall psychosocial wellbeing and postoperative societal reintegration. An ideal mandibular reconstruction should restore functional and aesthetic harmony not only for the skeletal deficit but also for the adjacent soft tissues and dentition, preferably with minimal donor site morbidity.

The mandibular reconstruction itself is just one aspect of a multidisciplinary, holistic treatment approach for the patient. The treating team should include experienced and subspecialty-trained reconstructive and ablative surgeons working alongside medical oncologists, radiographers, pathologists, radiotherapists, anaesthetists, psychologists and various dental, prosthodontic and rehabilitation specialists. These patients should therefore be managed in a specialist centre.

Mandibular anatomy

The mandible is constructed embryologically of two symmetric halves that are each formed from an individual ossification centre by intramembranous ossification. At birth, they are united at the midline by a fibrous symphysis; ossification is completed by the age of 2 years.^{1,2} It is the largest, strongest and only mobile bone of the facial skeleton. It articulates at the temporomandibular joints, each of which provides 6 degrees of freedom. This remarkable freedom of motion benefits from mechanical redundancy of the muscles of mastication.³

The mandible can be anatomically divided into one horizontal component (the symphysis and the body on each side), two vertical components (the angle, ramus, coronoid process and condylar process make up one vertical component on each side) and three processes (coronoid, condylar and alveolar). The mandible is elegantly designed to withstand the enormous forces of mastication. Thick cortical bone presides in areas that withstand unidirectional forces, such as at the condylar neck, and the bone possesses trabeculae where it needs to endure multidirectional forces, such as the alveolar process and condylar head.⁴ Pressure on the dentition is transmitted to underlying trabecular bone, which remodels throughout life according to dental loss, movement and the individual's masticatory habits. Adults possess 16 mandibular teeth: two central incisors, two lateral incisors, two canines, two first premolars, two second premolars and six molars. These occlude against their 16 maxillary counterparts.

The mandible transmits the bilateral inferior alveolar neurovascular bundles that deliver sensation from the dentition and related mucosa, and the chin and lower lip via the mental nerve. This inferior alveolar neurovascular bundle is the source of axial blood supply for the mandible; however significant blood supply is also derived from its periosteum and attached muscles. These muscles are involved in mastication, deglutition, oral continence, speech and, to a lesser extent, facial expression.

Mandibular defects

The most common indication for mandibular reconstruction is segmental bone loss. The vast majority of such defects result from soft tissue tumour ablations that require segmental bony resection for local control. Neoplasms of bone origin may also require segmental resection, but these are less common. Primary traumatic segmental loss is also uncommon; when it occurs it is usually due to a gunshot wound. Non-neoplastic conditions such as osteoradionecrosis, osteomyelitis and drug-related osteonecrosis (classically due to bisphosphonates) may also require

segmental resection for cure. Marginal mandibulectomies are generally not reconstructed as they do not inflict the same detrimental impact, since the mandible remains in continuity. Marginal mandibulectomies are, however, amenable to height augmentation using non-vascularized bone grafts or, in specific circumstances, vascularized bone flaps for dental rehabilitation.^{5,6}

Many systems have been proposed for classifying segmental mandibular defects. In our experience, the easiest and clearest is the scheme devised by Daniel.⁷ We have adopted its use routinely for audit, research and communication for ablation/reconstruction planning. This system always recognized the importance of the soft tissue deficit, as follows:

- 'isolated bone',
- 'compound' (bone and oral lining or skin),
- 'composite' (bone, oral lining and skin), or
- 'extensive composite' (bone, oral lining, skin and intervening soft tissues).⁷

The segment of bone that is missing is simply described according to the region affected (e.g. 'left angle to right parasymphysis'). Some additionally describe the defect in terms of the teeth that are resected with the segmental defect (e.g. 'left canine, right second premolar'); however, this is limited to dentulous patients and to the region between the mandibular angles.

Another popular system was proposed by Jewer *et al.*, who divided the mandible into 'H', 'C' and 'L' regions.⁸ A lateral defect of any length is described as an 'H' defect when the condyle is affected, or an 'L' defect when it is not. A 'C' defect is one that involves the central segment between the canines. For example, an angle-to-angle defect would be described as 'LCL' and a mandibular body defect as 'L'. The original classification did not consider the soft tissue deficit and was therefore later modified by adding the letters *o* for osseous defect only, *m* for mucosa, *s* for external skin and *ms* for combined surface defects.⁹ The loss of intervening soft tissue bulk is not accounted for by this system so it does not differentiate between *composite* and *extensive composite* defects.

Segmental mandibular reconstruction: principles and options

The reconstructive surgeon and multidisciplinary team will be faced with important decisions during patient selection. Some will be better served overall by a downgraded reconstruction whereas for others the best possible reconstruction should be offered.^{10,11} This decision will be affected by the patient's wishes, expectations and medical comorbidities, as well as the outcome of preoperative staging investigations. The intent of treatments (curative or palliative), and the planned ablative defect (dimensions and components), must be clearly communicated as these will all affect the choice of donor site(s) for tissue transfer. It should be noted that it is not unusual for resectional plans to change with intraoperative findings; patients should be made aware of this when providing informed consent to the overall procedure.

Segmental mandibular defects, however small, should not be collapsed for primary fixation. Even minimal malocclusion, which would be almost inevitable with this approach, causes chronic frustration for patients due to the lack of sensory feedback from unopposed teeth and symptomatic alterations in masticatory function. Likewise, no segmental mandibular defect should be left floating, as muscle actions become unopposed, the incongruence worsens, and the soft tissues contract and shorten, exacerbating the problem and complicating secondary reconstruction.

Segmental mandibular reconstruction should be completed within the same anaesthetic as an ablation, and primary healing achieved expeditiously so that adjuvant treatments are not delayed. Options include microsurgical and non-microsurgical reconstructions. Attention should also be directed at inferior alveolar nerve reconstruction, especially in benign cases, since lower lip numbness and/or dysaesthesiae are bothersome morbidities for patients, such as when sipping or testing the temperature of a drink, kissing, or when trying to maintain oral continence.¹²

Microsurgical free tissue transfer: choosing a single free flap for reconstruction

For patients who can undergo curative resection and microsurgery, the reconstructive procedure of choice for almost any ablative segmental mandibular defect is a free vascularized osseous flap that incorporates adequate soft tissues and inflicts minimal donor site morbidity. Desirable characteristics include high-quality bone stock, lengthy availability of donor bone, versatility in tailoring of the bony contour, flexibility in tridimensional inset of pliable and thin soft tissues, ability of the bone to support osseointegrated dental implants, and the option for a two-team ablative/reconstructive simultaneous approach. All of these features, and others, are fully provided by the fibula osteoseptocutaneous free flap, which has increasingly been accepted internationally as the best donor for segmental mandibular reconstruction.^{10,11,13–17}

A single fibula osteoseptocutaneous free flap will provide a good reconstruction for *isolated bone* and *compound* defects, and for many *composite* defects. Usually it cannot provide adequate soft tissues for *extensive composite* defects without inflicting too much donor site morbidity from extensive muscular harvest.^{10,17–19} The anatomy and harvest of this flap have been extensively described, but there are some key points that are important to stress.

First, the fibula should always be harvested with a skin paddle, even for *isolated bone* defects (when it should be harvested thin enough to allow comfortable primary closure of the donor site), as it will serve as an invaluable monitor of vascularity for the underlying bone.¹⁵ The skin paddle also serves to facilitate tension-free soft tissue closure at the recipient site and augment volume or contour if needed. Second, angiography of the donor leg is not a routine requirement; it should be considered if the pedal pulses are abnormal on clinical assessment or if there is a history of peripheral vascular disease or significant leg trauma.²⁰ Third, the vascularity of the skin paddle is reliable when correctly

harvested.¹⁵ Fourth, it is important not to harvest the proximal or distal 6 cm of fibula in order to preserve ankle and knee stability. Fifth, primary donor site closure should only be employed if the surgeon is confident that there is no risk of compartment syndrome from excessive tension; increasing postoperative leg pain and/or swelling, in particular, should be monitored for and a low threshold maintained for releasing the donor site for skin grafting if encountered. Sixth, it is important to exclude arteria peronea magna directly before harvest of the peroneal vessels; this is performed by inspecting the peroneal vessels for excessive size and by placing a microvascular clamp across the distal peroneal vessels early in the flap harvest to ensure maintenance of pedal pulses and absence of foot ischaemia. These last three measures remove the risk for the rarer but most significant potential donor site morbidities from fibula harvest. Other reported donor site morbidities from fibula harvest are also generally avoidable. For example, preservation of the neurovascular supply to the flexor hallucis longus muscle during fibula harvest and meticulous reapproximation of muscle origins to the remaining interosseous membrane under correct tension are important points of technique that effectively prevent toe flexion contracture and weakness. Additionally, suprafascial dissection of the skin paddle anterior to the posterior crural septum is important for preserving the superficial peroneal nerve branches. The preservation of paratenon is important to skin graft take over the peroneal tendons. Ling and Peng recently performed a literature-wide systematic review and provided level II evidence that the price of fibula harvest is low in terms of donor site morbidity as long as harvesting technique and donor site care are sound.²¹

Specific advantages of the fibula osteoseptocutaneous flap that make it ideal for mandibular reconstruction include its: (a) unmatched supply of strong, straight, lengthy bone of nearly uniform thickness and biomechanically sturdy triangular cross-section; (b) reliable acceptance of osseointegrated dental implants; (c) sizeable (2–3 mm) and lengthy pedicle; (d) thin, pliable, sizeable skin paddle (up to 22–25 cm in length and 10–14 cm in breadth) that can be inset into almost any configuration with respect to the bone; (e) potential usefulness as a chimeric or flow-through flap; (f) donor site that is an ideal nerve graft donor site for inferior alveolar nerve reconstruction if indicated; (g) distance away from the head and neck region, which invites a two-team approach to ablation and flap harvest; (h) tolerability of multiple osteotomies for bone shaping.¹¹

For these reasons, our first choice source of vascularized bone for segmental mandibular reconstruction is the left fibula osteoseptocutaneous flap and our second choice is the right fibula. It is therefore unusual for us to resort to any of the numerous alternative osseous flaps. These include harvests from the iliac crest, scapula, radius, rib, humerus and metatarsals. Although some prefer to use the vascularized iliac crest, the skin paddle is unsuitably bulky (even in slim patients) for lining the oral cavity and has limited mobility with respect to the bone.²² In addition, the pedicle is short, the deep circumflex iliac artery

supply is tenuous to the skin paddle,²³ and although the bone provides excellent bone stock it does not tolerate shaping osteotomies well. Donor site morbidity for the iliac crest includes protracted gait pain and/or disturbance, lateral femoral cutaneous nerve dysaesthesiae, abdominal wall structural problems such as hernia formation, and pelvic fracture, although, like for the fibula harvest, particular points of technique allow donor site morbidity for this flap to be significantly reduced.^{24–29}

Although the radial forearm provides a pliable, thin, hairless and reliable cutaneous or fasciocutaneous flap, the underlying radius should be regarded as a poor choice of donor vascularized bone for the mandible due to its intolerance of tailoring osteotomies, lack of bone stock, poor ability to support osseointegrated implants and the high risk for subsequent radius fracture. Some have resorted to bone grafting (using iliac crest bone graft) and/or plating the radius following its harvest in order to reduce the risk of secondary radius fracture, but this approach inflicts donor site morbidity in an additional location that is itself fraught with donor site morbidities, and prophylactic plating is not cost-effective.^{30,31}

The scapula donor site provides versatility regarding the soft tissue reconstruction, but the quality of the donor bone does not approach that of the fibula, and its location on the back is a major drawback since it precludes a two-team approach, prolonging the operation.

Technique of reconstruction: fibula osteoseptocutaneous free flap

The ablative and reconstructive teams should communicate clearly preoperatively to agree the likely defect and reconstructive requirements; this allows them to work simultaneously to reduce operative time. Once the ablative operation is completed, the premorbid occlusal relationship should be defined by maxillo-mandibular temporary fixation if dentition allows. This facilitates accurate shaping and fixation of the reconstruction plate. Alternatively, the reconstruction plate can be shaped against preoperatively fashioned mandibular templates or purchased pre-bent to standardized mandibular anatomy (available in different sizes). Maxillo-mandibular fixation can be released once each end of the reconstruction plate has been secured to the native mandible; tandem and full range of movement of the temporomandibular joints can thus be verified. Mini-plates may alternatively be chosen for fixation.

The recipient vessels are then prepared (usually branches of the ipsilateral external carotid and internal/external jugular systems, but may be contralateral or from the transverse cervical vessels if necessary) and the flap devascularized for shaping on a side table. Osteocytes are known not to be sensitive to a moderate period of ischaemia,³² which is usually well within 4 h for this flap, so we recommend that all osteotomies of the fibula should be performed at a side table. Unequalled surgical freedom is granted by freeing the fibula osteoseptocutaneous flap from the leg. It allows checking of planned osteotomy sites and angulations directly within the mandibular defect; rechecking of

completed osteotomies one-by-one against the defect before proceeding to the next osteotomy in case fine adjustments are required; draping of the flap skin paddle within the soft tissue defect to assess the site of the first osteotomy (which defines the length of fibula bone that will be discarded); freedom to rotate and manipulate the flap in hand to gain the most accurate appreciation of angulations in any plane; and trial inset(s) with temporary sutures to check and recheck any bony or soft tissue adjustments made on the flap.

The position of the first osteotomy should account for four main factors: first, the location of the blood vessels branching off the peroneal pedicle to supply the skin paddle; second, the required pedicle length (since this can be increased by dissecting it subperiosteally off the proximal fibula); third, there must be enough bone distal to the first osteotomy to complete the segmental defect reconstruction; fourth, it needs to be appreciated that every osteotomy will reduce available fibula bone length for reconstruction (this is particularly the case for wedge osteotomies, or if burring of osteotomy sites is required to refine accuracy of angulations). A fifth consideration is important when double-barrelling the fibula (useful for restoring either/both alveolar ridge height and facial height), which is that a segment of fibula no less than 3 cm in length should be removed subperiosteally at the folding hinge point and discarded.^{11,33} This is to allow double-barrelling without causing any kink, twist or stretch of the pedicle/periosteum between the barrels. All of these assessments are easier if the flap is in hand rather than still attached to the leg.

Osteotomies must be accurate and safe. They are best performed by the lead reconstructive microsurgeon with one assistant surgeon and one scrub nurse. The lead surgeon plans, marks, executes and checks the accuracy of all osteotomies. The lead surgeon holds one end of the fibula with a sharp-tipped bone holder (these do not crush the periosteum) using the non-dominant hand, and holds the oscillating saw with the dominant hand. The assistant surgeon stabilizes the other end of the fibula with another sharp-tipped bone holder and protects the pedicle (this is achieved by passing a flat instrument, such as a McDonald retractor, subperiosteally between the fibula and the pedicle in order to prevent the saw from damaging the periosteum/pedicle). The scrub nurse (or second assistant surgeon) is responsible for irrigation during osteotomies to prevent any bone heating, and irrigation of the flap tissues to prevent desiccation. Additionally, we recommend that osteotomies produce segments of fibula no less than 3 cm in length. Any shorter, and the blood supply to that segment will likely be threatened. A careful and sensible balance needs to be struck between exactly mimicking the curvature of the mandible and maintaining the blood supply to each fibula segment.

Insetting generally proceeds with the oral lining reconstruction first, followed by the bone. The soft tissue reconstruction deserves meticulous attention, as it is of at least equal importance to the bony reconstruction. Soft tissue deficiency is poorly tolerated in the head and neck region, especially when cavities

are left unfilled as this invites fluid accumulation and infection. It is important that the oral lining reconstruction is water-tight so as to avoid salivary leakage around the mandible reconstruction and into the neck. Additionally, soft tissue tethering places a check-rein on the patient's functional potential. Poor tongue mobility, for example, may result from insufficient tissue redundancy or pliability. Conversely, an overly bulky flap may hinder a functional residual hemi-tongue and yet may be necessary for a subtotal glossectomy reconstruction to achieve occlusion against the palate. Likewise, postreconstruction trismus may be the result of contracted or inadequate buccal or retromolar trigone lining, whereas an overly bulky reconstruction in these subsites will lead to dental trauma to the flap. Accordingly, untethered soft tissues with appropriate redundancy and yet without excessive bulk, is the desired soft tissue reconstruction goal.¹⁰ Long-term soft tissue shrinkage should be expected and accounted for when designing the soft tissue reconstruction, particularly in patients who will receive adjuvant radiotherapy. Additional mobility of the skin paddle with respect to the bone is possible by selectively incising the septum either side of its supplying vessels. For *isolated bone* defects, the skin paddle can be concealed intraorally or submentally within an incision used during the ablation and excised at a later date if necessary.

Bony fixation needs to be rigid in order to allow postoperative rehabilitation of the temporomandibular joints. Monocortical screws are recommended to safeguard blood supply; they can gain tip purchase of the second cortex for additional stability but must not encroach upon the overlying periosteum. Microsurgical anastomoses are performed after all inset(s) is complete (Figure 26.1).

Microsurgical free tissue transfer: performing a double free flap reconstruction

Although a fibula osteoseptocutaneous free flap can import a sizeable fasciocutaneous paddle and, if absolutely necessary, some muscle (e.g. soleus and/or flexor hallucis longus) with the bone, *extensive composite* mandibular defects generally require even more volume. Recruitment of additional muscles from the leg to maximize the soft tissue volume available with the fibula increases the donor site morbidity. In such circumstances, a double free flap can provide a superior reconstruction.^{10,17}

Some may argue that the morbidity of having one donor site is better than having two. However, when one donor site is large, has significant muscular harvest for volume and cannot be primarily closed, then its morbidity could actually be more severe than using two smaller donor sites that each preserves donor site function. In effect, the volume and morbidity requirements for a large complex defect are shared by two donor sites rather than inflicted on only one.¹⁰

By performing a double free flap, the best donor osseous and soft tissue characteristics can be selected independently to satisfy the requirements of the defect. This improves inset(s), manoeuvrability and conformability, thus avoiding critical flap

Figure 26.1 Compound segmental mandibular defect reconstructed with a fibula osteoseptocutaneous flap. (a) Squamous cell carcinoma of the left lower gum. (b) Compound segmental mandibular defect stabilized with a reconstruction plate (note the associated extensive intraoral mucosa defect). (c) Skin island of the fibula osteoseptocutaneous flap used for intraoral mucosa lining reconstruction. (d) Redundant portion of the skin island de-epithelialised and used for soft tissue augmentation over the fibula–reconstruction plate construct. (e) Appearance immediately after revascularization of the fibula osteoseptocutaneous flap at the reconstruction site. (f, g) Appearance at 6 years follow-up.

folding even with large volumes of tissues. Our usual choices for a double free flap mandibular reconstruction are the fibula osteoseptocutaneous flap for mandible with oral lining and the anterolateral thigh flap for cheek volume and external facial coverage. Both flaps are far away from the head and neck region, and therefore a two-team approach is possible throughout the double flap procedure.

The main deterrent to performing a double free flap in most centres is probably the length of surgery. However, this can readily be reduced with efficient team work; indeed it has been demonstrated in many centres, including our own, that the difference in operating times between single and double free flap procedures can be negligible.^{10,17} To achieve this, two operating teams should work simultaneously throughout the operation. First, the ablative and the first reconstructive

team work together; second, the second reconstructive team works alongside the first reconstructive team until the end of the operation. Accordingly, the operation will begin with the first reconstructive team raising the flap that will be used to line the oral cavity (usually this would be the fibula osteoseptocutaneous flap) while the ablation is underway. When ablation is complete, the second reconstructive team raises the second flap (usually the soft tissue free flap that will be used to fill the cheek and reconstruct the facial skin defect) while the first free flap is osteotomized, inset and revascularized by the first reconstructive team. By the time the first free flap is inset and revascularized, the second free flap should be ready for inset and revascularization by the first reconstructive team while the second reconstructive team closes both donor sites.

Osseointegration of dental implants

The bone stock and dimensions of the fibula osteoseptocutaneous free flap are consistently adequate for implant placement.³⁴ Whether performed primarily or secondarily, osseointegration of dental implants involves three distinct stages. At the first stage, the implant fixture is set into the bone and the internal thread is protected with cover screws. The first stage can be performed in select patients as part of the microsurgical mandibular reconstruction (primary osseointegration); in others it can be offered as part of the postoperative rehabilitation program (secondary osseointegration). We have utilized primary osseointegration into

free osseous flaps for many years and have published our outcomes in single and double-barrelled fibula osteoseptocutaneous free flaps.^{11,33,35–38} Double-barrelled fibula osteoseptocutaneous flaps are useful for simultaneously achieving the facial and alveolar process heights for aesthetics as well as dental rehabilitation. Vertical distraction osteogenesis is another method that is used for this purpose, but requires secondary osseointegration instead and we have found that it generally has a higher complication rate.³⁷ At the second stage, the cover screws are removed, healing abutments are screwed into the fixtures, a palatal mucosal graft is secured around the abutments and the graft is protected with a removable stent. At the third stage, the prosthesis is fitted (Figure 26.2).

Figure 26.2 Recurrent ameloblastoma of the mandible segmentally resected and reconstructed with a fibula osteoseptocutaneous flap with simultaneous osseointegrated dental implantation for dental rehabilitation and sural nerve graft for restoration of lip and chin sensation. (a) Resultant mandibular defect reconstructed with a fibula osteoseptocutaneous flap and simultaneous osseointegrated dental implantation. Proper occlusion confirmed with guiding screws. (b) Mental nerve defect reconstructed with a sural nerve graft. (c) Appearance after initial reconstruction. (d) Palatal mucosa graft to replace the skin island around the abutments. (e, f) External and occlusal appearance 3 years after surgery. (g) Panorex radiograph 15 years after surgery.

Non-microsurgical techniques

These include grafts, prosthetic materials and pedicled flaps in various combinations and should be mentioned for completeness. They generally offer downgraded reconstructions in comparison to what can be achieved with microsurgical free tissue transfer, but may be appropriate primary reconstruction choices in patients with particularly poor oncological prognoses and/or an array of significant medical comorbidities.¹¹

Non-vascularized bone grafts still have a place in modern segmental mandibular reconstruction for small *isolated bone* defects in biomechanically favourable locations (body or ramus), which have not undergone and will not undergo radiotherapy, which have minimal risk of infection, and are surrounded by healthy, well-vascularized soft tissues. This combination of requirements is rare for non-traumatic segmental defects, but more common for marginal defects, such as those requiring alveolar ridge height augmentations for dental restoration.⁵

The most common prosthetic reconstruction is a substantial bridging mandibular reconstruction plate. This usually would require additional soft tissue coverage, such as with a pectoralis major myocutaneous flap. Alternatively, microvascular free tissue transfer from a location distant to the head, such as from the anterolateral thigh, allows a two-team approach and a total operating time that is similar to using a regional pedicled flap. Nevertheless, whatever method of soft tissue coverage is chosen, plate reconstructions are non-biological and therefore have major disadvantages, including plate/screw fatigue, failure and extrusion, especially amidst infection or radiotherapy.³⁹ Regional vascularized bone can be imported from the ribs, clavicle or scapula, with the pectoralis major, sternocleidomastoid or trapezius flaps, respectively, but have significant limitations in terms of poor bone quality, fragile osseous blood supply, inadequate flexibility in bone inseting, and significant donor site morbidity. Nevertheless, these may provide 'lifeboat' options such as following multiple free flap failures.

Complications and their management

A free flap success rate in excess of 95% for the head and neck region should be the benchmark. But still, despite best efforts, some free flaps will fail. The reader is directed to an in-depth study that addressed the management of the failed free flap in the head and neck region.⁴⁰ Our overall recommendation is that, usually, a failed free flap in the head and neck region should be replaced by another similar free flap. This applies particularly for a failed fibula osteoseptocutaneous free flap used for mandibular reconstruction. Once local wound infection has been controlled and the patient has been reoptimized from the anaesthetic perspective, it is recommended that the contralateral fibula be used for segmental mandibular reconstruction as a second attempt.⁴⁰ Performing a downgraded reconstruction in a candidate who had been deemed suitable for a high-quality

fibula osteoseptocutaneous free flap reconstruction is a mediocre alternative. Interestingly, failed free flaps in the head and neck region that were then managed by regional flaps had a higher subsequent complication rate than those that were replaced by a second free flap. The success rate for a second free flap was 94.1% in this series.⁴⁰

The accumulation of any fluid in the neck, such as saliva, haematoma, abscess or lymph, needs to be dealt with expediently. The wound must be opened, irrigated and debrided as necessary in the operating room to prevent flap failure and still allow timely wound healing so that adjuvant treatments are not delayed. Carotid artery blow-out is a feared complication that mandates healthy coverage of the major neck vessels following any regional reconstruction.

Later complications include metalwork exposure/fatigue/fracture and radiation-induced soft tissue shrinkage/contractures, osteoradionecrosis, osteomyelitis and the various specific complications related to osseointegrated implants, including implant loosening, malpositioning and associated soft tissue problems.

Conclusions

The requirements for a high-quality segmental mandibular reconstruction are clear. The anatomy, including the bone, soft tissues and joints, needs to be restored as closely to its normal state as possible, in the fewest surgical stages and as quickly as possible, in order that musculoskeletal functional, aesthetic, dental and psychosocial impacts are minimal to the patient. In addition, wound healing must be completed rapidly, which means without complications, so that life-saving adjuvant treatments are not delayed. This is a challenge, but when armed with the above techniques and principles, one can provide a high-quality reconstruction for many patients.

CHAPTER 27

Maxillary reconstruction

Achilleas Thoma, Michael Gupta and Stuart Archibald

Division of Otolaryngology-Head and Neck Surgery and Division of Plastic Surgery, Department of Surgery, McMaster University, Hamilton, Canada

Introduction

Indications

Reconstruction of the maxilla (or midface) is necessary due to defects caused by tumours (malignant or benign), trauma or congenital defects. By far the most common of these are those caused by cancer and hence this chapter will focus on this aetiology.

Comprehensive reconstruction of maxillary defects requires restoration of lost function and form. Functional impairment may involve speech, eating and oral hygiene, but may extend to breathing and vision. Form loss can further alter facial proportions, symmetry and motion. Reconstructions need to take into account which functional losses must be corrected and in what priority, and which alterations in form can and should be corrected. The bones of the midface provide the underlying shape of the face, over which lie the muscles of facial expression and integument that give us each our unique facial appearance. These bones separate the contents of the orbits, nasal cavity, sinus and oral cavities, and provide support for the maxillary dental arch inferiorly, the orbits and sinuses laterally, and the skull base superiorly. In general terms, any reconstruction is aimed at restoring the compromised separations and the lost supports. The reconstructions span the spectrum from prosthetics to free tissue transfers to combinations of these, and therefore can range from relatively simple to extremely complex. Most cases require a 'team' approach. In this chapter we attempt to set out the principles that guide such reconstructions, and to provide some examples.

Historical evolution of maxillary reconstructions

The advent of microsurgery in the late 1970s and early 1980s can be considered a seminal time period in which a quantum leap occurred in our ability to reconstruct the challenging deformities left after maxillectomy. Until this time period, the mainstay of reconstruction in most maxillary defects was the lining of the defects with skin grafts and the use of obturators or some type of maxillary prosthesis. For the smaller defects the obturators

provided separation of the oral and sinonasal cavities and allowed 'normal speech'. The provision of prosthetic teeth in conjunction with the obturators provided the ability to eat. With the small defects, there is role for obturators even today. Obturators may obviate complex reconstructions, a distinct advantage in frail patients. When faced with larger defects, however, the obturators were not as useful, primarily related to poor fitting and loosening.¹

Historically, multistaged flaps² led to pedicled, axial-pattern, fasciocutaneous flaps³⁻⁵ and their application to maxillectomy defects.⁶

The next evolutionary step in the maxillectomy reconstruction was the introduction of the pectoralis major myocutaneous flap.⁷ This, however, had limited use due to the high reach needed and the random nature of the circulation of the distal portion of this flap, and the downward drag of these flaps, causing the reconstruction to change over time.

The use of pedicled flaps in the premicrosurgery era (and in some cases overlapping with it), was not as successful due to the restrictions imposed by the base of the flap, the reach of the flap to its target area and the cosmetic appearance in this anatomically sensitive area.

It is in the massive defects that the introduction of microsurgery was a major advance in the rehabilitation of these patients. The ability to transfer autogenous tissue, including bone and soft tissue, allowed us to reconstruct what is missing.⁸⁻¹³

This chapter attempts to cover the state of the art in maxillary reconstruction. We are cognizant though that with the few recent composite tissue allotransplantations (CTAs) reported to the midface globally we may be at the dawn of a new era in maxillary reconstruction.¹⁴⁻¹⁹ Presently midface CTAs have not been performed in postcancer reconstructions to our knowledge. The few reported cases in trauma situations show amazing results that will definitely dwarf the autogenous tissue microsurgical reconstructions from both the functional and cosmetic point of view. As soon as the issue of 'safe immunosuppression' is achieved it is expected that CTA will supplant any other reconstructive method in the extensive maxillary defects.

It is to be understood that up to now, only lower level evidence exists in the literature in guiding reconstructive surgeons in the selection of appropriate techniques. This chapter is written based on this lower level evidence. Presently, no single cancer centre will have many midface reconstruction cases to allow investigators to produce high-quality level of evidence.

Anatomic considerations

To understand the intricacies of maxillary reconstruction one needs to understand the three-dimensional anatomy of the maxilla. The maxilla has been described as a hexahedron with a box with six walls.^{13,20,21} The roof of this box is formed by the floor of the orbit and its floor is the hard palate and alveolar ridge. Its medial wall is made by the lateral wall of the nasal cavity. The anterior, posterior and lateral walls are made by the vertical and horizontal bony buttresses. These walls contain in their centre the maxillary sinus. The maxillary bones are reinforced by the two horizontal buttresses (inferior orbital rim and the maxillary arch) and the three vertical buttresses (nasomaxillary, zygomaticomaxillary and pterygomaxillary). The muscles of facial expression and mastication minimally overlie the maxilla.

Tumours arising in the midface and maxilla can extend and involve tissues beyond its boundaries. In addition to the maxilla and overlying soft tissues they may include the contiguous areas of the orbit, skull base, nose, mandible and parotid gland.²² Consequently in a maxillectomy procedure contiguous structures that may be resected include: soft palate, lips, nose, cheek and overlying skin, orbital contents, zygoma and pterygoid plates.

Maxillectomy therefore represents a group of diverse defects ranging from a minor oro-antral and/or oronasal defect of the palate to a major defect bounded superiorly by the anterior skull base and inferiorly by the tongue.²³

The morbidity associated with maxillectomy is variable depending on the extent of the resection and can affect deglutition, speech, vision, maintenance of hygiene from debris accumulation and equally important facial disfigurement.

Reconstruction methods

General principles

The three main goals of maxillary reconstruction can be listed as follows:

- separate intracranial, orbital, nasal, and oral spaces;
- restore function; and
- restore a reasonable cosmetic appearance.

The most important goal is to provide safe separation between a contaminated 'nasal space' and the 'clean' anterior cranial fossa. Failure to accomplish this successfully will lead to meningitis and ultimately the death of the patient. There is a need to separate the orbital contents from the wide open sinonasal space.

Under the rubric 'function', there are a number of objectives. The key ones are: (a) to stabilize the floor of the orbit and avoid dystopia with subsequent diplopia; (b) to leave a functional nasal airway for breathing; (c) to separate the oral from the nasal cavities to allow proper eating and intelligible speech; (d) to provide a stable bony maxillary arch to permit acceptance of osseointegrated implants or soft tissue-borne prosthesis for chewing and eating.

The cosmetic appearance will be determined to a great extent by the choice of a suitable flap that takes into consideration the colour match, texture and volume of the autologous tissue transferred. It is in this domain that CTA hopefully will provide the next quantum leap in maxillary reconstruction.

In complex defects the reconstruction may apply to multiple subunits.²⁴ The ranking of reconstruction goals for complex defects can be found in Table 27.1.

Classification systems

Because of the various permutations of defects that can be produced after extirpation of cancer, which may include bone, bone and soft tissues, bone and orbital contents, bone and palate, bone and nasal lining, etc.) different methods of reconstructions are necessary. Over the years a number of surgeons and prosthodontists have introduced various classification systems of these, depending on their experience, technical skills or specialty training, without achieving consensus.^{10,13,22,23,25–34} The classification systems were based on the procedure performed,^{13,22} the tissue loss,^{25,28,29,31} the prosthodontist perspective post surgery^{25,26,31} and the surgical resection.^{10,13,22,27–30,32–34}

As a result of the different perspectives taken in dealing with the maxillectomy defects (i.e. surgical versus prosthodontic) and the failure to address all anatomical issues of the defect, no universal classification has been accepted so far.

In a recent systematic review of the classification systems Bidra *et al.*¹ identified these weaknesses and suggested six criteria, with the acronym of DOC-SAM, that are necessary for universal description of maxillectomy defect (Table 27.2).

These criteria take into consideration the importance of 3D reconstruction of the defects and the future prosthodontist rehabilitation. These criteria are: (a) dental status, (b) oro-antral/nasal communication status, (c) contiguous structure involvement, (d) superior–inferior extent, (e) anterior–posterior extent and (f) medial–lateral extent.

These criteria, if adopted, should definitely improve the communication among healthcare professionals dealing with the maxillectomy defects and add clarity to the reporting of defects and results of reconstruction.

Algorithms for maxillary reconstructions have been published but again these are prone to selection biases based on the authors' subspecialty, interest and experience.^{21,29,35}

As the focus of this chapter is maxillary reconstruction and directed towards plastic surgeons, we selected the Cordeiro classification in this chapter. We are aware that this classification system does not include a localized lateral hard palate resection

Table 27.1 Ranking of reconstruction goals for complex defects

Priority	Subunit	Goal	Solution
1	Upper	Prevent meningitis or brain abscess	Restore lost barrier between sino-nasal complex and anterior cranial fossa
2	Lower	Restore oral functions of eating and speech (in some cases, goal no. 6 is included here)	Replace the lost barrier between sinonasal complex and mouth, either with soft tissue alone, with both soft tissue and bone, or with a prosthesis secured in one of two ways
3	Central	Restore central midface surface contour (with restoration of sensation and motion very secondary goals). In some cases, goals nos 5, 6, or both are best included here	Restore the external soft tissue with tissue of sufficient subcutaneous thickness, and skin with acceptable texture and colour match
4	Upper	Prevent diplopia	Restore support to the orbital contents with a soft tissue layer only (e.g. sling, fascia patch, skin graft) or with antral space obliteration (cf. no. 5)
5	Central	Eliminate the nasal and sinus cavities as a common chamber above an intact or reconstructed palate, to avoid foul-smelling, inaccessible crusting	Replace the lost lateral nasal wall and/or obliterate the antral space with soft tissue
6	Central and lower	Restore anterior projection of the maxillary arch and vertical height of the midface (nasomaxillary, zygomatico-maxillary and pterygo-maxillary buttresses). Decide on goals of dental rehabilitation (none, tissue-borne prosthesis, or osseous integrated implants)	Depending on dental rehabilitation goals, may choose either to restore the lost dimensions with soft tissue only or to replace the anterior or posterior buttresses of the maxillary arch with suitably robust bone. This is accurately positioned, firmly secured, and covered with a skin paddle
7	Upper	Provide shape and support to the orbit and symmetry to the peri-orbita, including canthal ligaments. If orbit exenterated, decide how to deal with the cavity	Restore zygomatic buttress and/or horizontal buttress of the infraorbital rim. Consider whether flap is to obliterate/ cover the orbit or whether a prosthesis is to cover the orbit, if so, should prosthesis be bone-anchored or soft tissue borne? ³³

for what is primarily an oral cancer, yet involves the lower maxillary infrastructure. We are also aware that the classification system does not include central or bilateral resections. Nevertheless although this system does not meet all of Bidra's criteria, until a better system is introduced it will suffice. In any case it is the most widely used as it is based on a relatively large volume of cases and it encompasses the clinically important types of

defects that we are likely to encounter in our surgical practices. In addition the authors provide an accompanying algorithm for flap selection per type of defect.²¹ This classification system is shown in Figure 27.1. It includes type I, which is a limited maxillectomy in which the anterior and medial walls of the maxilla with associated skin and soft tissues are resected; type II, which is a subtotal maxillectomy defect in which the lower five walls of the maxilla including the palate are resected; type IIIa, in which all six walls of the maxilla, including the floor of the orbit and hard palate, are resected; type IIIb, in which all six walls of the maxilla, including the floor of the orbit and orbital contents, are resected; and type IV which is an orbitomaxillary defect. This is the same as type IIIb with the exception that the palate remains intact.

The Cordeiro algorithm is shown in Figure 27.2. This algorithm shows the choice of only two free flaps for the reconstruction of these defects. Although in general we agree with this simplification¹³ (Cordeiro *et al.* only use two free flaps; radial forearm or free rectus abdominis), there are occasions where other free flaps may need to be chosen. Archibald *et al.*¹² provided the ranking of various free flaps chosen for midfacial reconstruction by their reconstructive microsurgeons in their institution (Table 27.3).

With careful consideration of the missing tissues and their meticulous reconstruction one can attain reasonable functional results. In a large series of 246 maxillary reconstructions, 95% of patients achieved greater than 80% speech intelligibility (with some of them requiring obturation in addition to free flap) and 70.8% were able to feed themselves with unrestricted diet.³⁵

Figure 27.1 Corderio classification system for the maxillectomy defect. (a) Type I, (b) type II, (c) type IIIa, (d) type IIIb, (e) type IV.

Complications and management

There are many complications that can occur in the course of maxillary reconstruction. In general terms they can be classified into medical or surgical complications.

As the oncologic patients are in general elderly they have associated medical problems that can complicate their recovery. Large recent studies have found as many as 37.8% of patients suffered some perioperative complication after maxillectomy reconstruction.³⁵ Consequently, it is important that a patient's medical condition is optimized prior to surgery and followed carefully post operatively. Consultations from internists, anaesthesia or other subspecialists may be important in both preoperative and postoperative period.

Of the surgery-related complications, free flap failure is among the most dreaded. In a recent large series total flap failure was reported to be 3.3%.³⁵ As free flap failure is a serious complication, every effort should be made to achieve success. This is a case where the most expert microsurgeon should perform the microvascular anastomoses to ensure vessel patency. When the reconstructive plan is first developed, a back-up flap should be identified in the unlikely event of total free flap failure. During surgery care should be taken to protect the donor site of the back-up flap.

Fistula (oronasal, oro-antral, orocutaneous, nasocutaneous) is another potential complication. A rate of 7.5% has been reported in the largest series of maxillary reconstructions

(*N* = 246) reported recently.³⁵ If a flap has been used for the maxillectomy defect, and tissue redundancy exists from the primary flap, this tissue can be used to close the fistula.

Midface projection can be lost if traditional bone graft has been used and this was not adequately covered with vascularized tissue. This problem can be avoided by using vascularized bone graft with robust circulation. One must ensure that the maxillary arch is established by using templates and the proper 'carpentry' of the vascularized bone graft intraoperatively. Recent innovations with computer-assisted facial transplantation may help minimize this problem in the future.²⁹

Malocclusion can be a problem if the maxillary arch is not properly aligned. Preplating of the maxilla before the tumour resection, if possible, should be contemplated to maintain the 3D spatial orientation of the future bone graft.

CSF leak can be a serious complication, leading to meningitis. This is reported to occur in 1.2% of cases,³⁵ and is more likely to occur if the defects include the skull base. In such cases a neurosurgeon should be part of the team from the beginning to ensure dural seal. From the reconstructive point of view, the dural seal can be reinforced from below by choosing a myocutaneous flap (e.g. rectus abdominis). Muscle flaps have the added advantage of sealing irregular surfaces and deliver antibiotics to critical areas such as the skull base.

Diplopia usually is the result of failure to adequately reconstruct the floor of the orbit. Non-vascularized bone grafts can be

used provided vascularized muscle is introduced to cover the bone. Titanium mesh can also be used. The rate of diplopia/dystopia as a complication of reconstruction was found to be the same for those patients who had bone or titanium mesh recon-

struction at 1.7%.³⁵ Alternatively, a vascularized bone graft can be used for this purpose.

Social isolation and seclusion can be another serious problem if the reconstruction is aesthetically inadequate. Attention to

Figure 27.7 Case 5: A 74-year-old female patient with adenoid cystic carcinoma of the right maxilla. See text for details.

details and proper selection of flaps can go a long way to preventing this problem. Patients should be alerted to the need of future revisions.

Case studies

Below we show some cases of maxillary reconstruction from our centre.

Case 1

A 39-year-old female presented with squamous cell carcinoma (Figure 27.3a) of the maxillary sinus which did not respond to radiotherapy. Radiation changes are evident on facial skin over the right maxilla. Following right maxillectomy and orbital extenteration (Figure 27.3b) (Cordeiro defect IIIb) she was reconstructed with a three-panel scapular flap to provide separation of two cavities (i.e. nasal, oronasal) and to provide coverage for the orbital defect (Figure 27.3c,d). Figure 27.3e shows final result. The bulk and stiffness of the flap eliminated the dead space of the maxillectomy defect. Figure 27.3f shows the intraoral panel of the scapular flap.

Case 2

A 68-year-old female with poorly differentiated squamous cell carcinoma of the right maxilla extending to overlying skin, orbit and oral cavity (Figure 27.4a). After bi-frontal craniotomy and supraorbital exploration, right maxillectomy and orbital exenteration was performed (Cordeiro IIIb defect) (Figure 27.4b). Duroplasty was performed with temporal fascia. Reconstruction was performed with a rectus abdominis myocutaneous flap from which two separate skin panels were used: one to separate the sinonasal cavity from the oral cavity (Figure 27.4c) and the second to provide external coverage to the facial orbital defect (Figure 27.4d). The bulk of the muscle provided dural seal superiorly.

Case 3

A 63-year-old male with squamous cell carcinoma required resection of the maxillary alveolus, portion of the hard palate and nasal floor, complete rhinectomy (Cordeiro defect II) (Figure 27.5a). Figure 27.5b shows a template of the defect and Figure 27.5c the outline of the template on the forearm. The hatched area was eventually de-epithelialized to separate the oral from the nasal panels of the flap. Figure 27.5d shows the doubly osteotomized radial forearm osteocutaneous flap to reconstruct the alveolus. The alveolus was reconstructed using mini plates (Figure 27.5e) and the forearm skin wrapped around the bone graft to reconstruct the floor of the nose and palate (Figure 27.5f). The lip defect was reconstructed with twin Karapandzic flaps (not shown here). The nasal defect was reconstructed with a forehead flap at the same operation. Figure 27.5g shows the final result of this difficult defect.

Case 4

A 71-year-old woman with recurrent basal cell carcinoma required partial right maxillectomy (Cordeiro defect II). Reconstruction was achieved with a three-panel scapular fasciocutaneous flap (Figure 27.6a,b). One panel was used for the lateral nasal wall (Figure 27.6c, d showing inseting), a second panel was used for the intraoral defect (Figure 27.6e) and a third panel was used for the external coverage (Figure 27.6f). No bony reconstruction was used in this case.

Case 5

A 74-year-old female patient with adenoid cystic carcinoma of the right maxilla required orbitomaxillectomy proceeded by craniotomy to establish the extent of the tumour superiorly (Cordeiro defect IIIb). Figure 27.7a shows the defect immediately after the resection. Figures 27.7b and c show the anterior-posterior and vertical extent of resection, respectively. Figure 27.7d shows the resected specimen. Reconstruction was achieved with a radial forearm osteocutaneous flap (Figure 27.7e). Figure 27.7f shows the alveolar and palatal reconstruction. Figure 27.7g shows the final result with external eye prosthesis.

CHAPTER 28

Pharyngeal reconstruction

Ross D. Farhadieh^{1,2} and Wayne A.J. Morrison³

¹Panthea Plastic Surgery Clinics, Sydney & Canberra, Australia

²Australian National University, Canberra, Australia

³O'Brien Institute and Department of Surgery, University of Melbourne, Melbourne, Australia

Introduction

The upper aerodigestive (UAD) tract is an intricate maze of alleyways, muscular tubes and cords that allows humans to have a common functional pathway for oral intake, breathing, as well as harmonizing vibrations into speech. Articulation of speech is dependent on the symphony of functions of these passages, influenced by the larynx, epiglottis, pharyngeal walls, soft and hard palate, the tongue musculature, salivation, lip seal or oral competence and dentition as a tightly ordered orchestra. Many of these functional elements involve the pharynx.

The posterior reaches and ramifications of the UAD tract coalesce into a continuous 15-cm-long muscular collecting tube, the pharynx, which begins in continuity with the nasopharynx superiorly and connects to the oesophagus inferiorly. It extends from the skull base to the oesophagus and comprises three parts: upper or nasopharynx behind the nose, middle or oropharynx behind the mouth, and lower or hypo- or laryngopharynx behind the epiglottis and larynx.

Pathology

Pharyngeal cancers are predominately squamous cell carcinoma (SCC) and are of two types: HPV+ related to human papilloma virus (better prognosis) and HPV– usually linked to alcohol and tobacco. Risk factors include alcohol and tobacco, exposure to Epstein–Barr virus and Chinese ethnicity, especially for nasopharyngeal carcinoma. Organ preservation has become the main aim in the management of UAD tract malignancy. Fortunately, early stage disease can be effectively treated conservatively with radiotherapy or chemo-radiation combination so that function can largely be preserved. Given the morbidity of surgery in this most sophisticated functional zone, its place is increasingly

reserved for advanced stage disease or in salvage treatment after failure of non-surgical protocols. Sadly, most patients present at advanced stages and are associated with poor overall survival. Between 70 and 85% have stage 3 or stage 4 disease at presentation and 5-year survivals are reported around 15–35%.^{1,2} The reality is that most surgery is palliative and although the prime focus here is inevitably on removal of the cancer and reduction in the risk of local recurrence, the overall picture must be on the quality of survival. By contrast, nasopharyngeal cancers have a better prognosis as they are mostly responsive to radiotherapy and rarely require surgical resection or reconstruction.

Anatomy

The nasopharynx is open to the nasal cavities anteriorly and extends from the base of the skull superiorly to the upper surface of the soft palate where it becomes the oropharynx. The oropharynx communicates with the mouth anteriorly and includes the soft palate, the tonsils and the tongue base posterior to the circumvallate papillae. The oropharyngeal tube extends from the soft palate above to the hyoid below. The hypopharynx is continuous below the oropharynx, extending from the level of the hyoid bone to the oesophageal inlet. The larynx lies in close anterior proximity. The thyrohyoid membrane through which the internal branch of the superior laryngeal nerve gains access to the larynx is located supero-laterally. The detailed anatomy of the UAD tract can be found in specialized texts. Anatomically, the area has a rich lymphatic drainage to the jugular chains as well as the retropharyngeal nodes and the node of Rouvière^{1,3} with frequent crossing of the midline. The pharyngeal muscular tube, which spans from the base of the skull to the C6 vertebra, comprises circular fibres that form constrictions to propel contents into the oesophagus and longitudinal fibres that lift the walls of the pharynx during swallowing.

Indications for surgery and reconstruction

Most commonly, major UAD tract defects result from surgical ablation of malignancies. It is accepted that X-ray therapy is just as effective as surgery for eradication of early disease, and because X-ray therapy is less destructive to function, it is the preferred modality of treatment. Surgery is therefore reserved for advanced stage or recurrent cancers and will be inevitably destructive. The principles of wide oncological resection, the proximity of the vital structures and the protection of the upper airway patency, speech and deglutition dictate the indications for reconstruction of any significant UAD tract defects. Many pharyngectomies for advanced disease are associated with combined laryngectomy. Thus most advanced neoplasms involving the oropharynx, hypopharynx or cervical oesophagus will result in a pharyngeal defect requiring reconstruction.

Classification of pharyngeal defects

A useful classification of pharyngeal defects was devised by Disa *et al.*⁴

- Type I: Partial defects involving less than 50% of the pharyngeal circumference.
- Type II: Circumferential defects or those greater than 50% of pharyngeal circumference.
- Type III: Extensive non-circumferential defects involving multiple other anatomical sites

As with all classifications, it has shortcomings. It does not distinguish whether partial defects involve the larynx or base of tongue. It also assumes that any defect greater than 50% of the circumference should be considered a circumferential defect and this has implications for the algorithm-directed surgeon.

Historical perspectives

The first attempts at pharyngo-oesophageal reconstruction date back to the nineteenth century. These proved notoriously unreliable, with chronic aspiration, haemorrhage and early death in the postoperative course followed by stricture formation in those who survived the immediate aftermath of the surgery. This led to a loss of enthusiasm for reconstruction until Wookey rekindled interest in 1942 with a random pattern anterior neck skin flap to re-establish the UAD tract.¹ His two-stage reconstruction included using the cervical skin raised as a random flap sutured to the upper and lower ends of the defect, but left open anteriorly thereby exteriorizing the pharynx and oesophagus. The sulcus thus created was closed five weeks later at a second-stage operation. The next surgical leap came when Bakamjian described the more reliable axial deltopectoral flap, based medially on what has subsequently been shown to be the upper 2nd and 3rd internal thoracic artery perforating branches.⁵ It was, however, still a two- or three-stage treatment and was not uniformly reliable.

In 1979, Ariyan's description of a tubed myocutaneous pectoralis major flap finally made possible a single-stage ablative reconstruction with a more predictable outcome.⁶ Subsequently, both the trapezius and latissimus dorsi myocutaneous flaps were described as alternatives for a single-stage reconstruction, but not surprisingly did not achieve significant popularity.^{2,3}

Parallel with these skin tube developments, more reliable pedicled interposition gastrointestinal reconstructions were being attempted as far back as the 1930s, their primary role, however, was in total oesophagectomies. Adaptation of the Ivor-Lewis gastric pull-up to the cervical oesophagus and pharynx was one such procedure, which has survived as a mostly reliable option into the modern era. In addition to the gastric pull-up, the spectrum of these pedicled flap reconstructions included the left colon and the seldom used pedicled jejunum.^{7–10}

In 1959, Seidenberg¹¹ reported the first successful harvesting and transferring of a jejunal free flap using microsurgical techniques, reportedly with threaded 6-0 silk sutures under loupes magnification. His patient died 5 days postoperatively from a massive cerebrovascular accident, but the first successful human free flap was found to be viable at the time. The following year Hiebert and Cummings¹² performed an uneventful gastro-antral free graft joining 2-mm-diameter gastro-epiploic vessels to the superior thyroid artery end to side and facial vein end to end. They noted the report of Jacobson and Suarez, the acknowledged founders of microvascular technique that occurred subsequent to their procedure, recommending using a microscope. These feats were performed at least a decade before the tidal wave of microsurgery began, with the work of Buncke *et al.*,¹³ Daniel and Taylor,¹⁴ O'Brien *et al.*¹⁵ and others who used other tissues, including omentum and skin. Soon, microsurgical free tissue transfer was to become a first-line mainstream reconstructive option.

Microvascular technique brought with it the promise of a reconstruction not bound by restraints of pedicle length or random proportions. The reliability of an axial flap transfer into the defect revolutionized the approach to major reconstructive challenges. Gastro-omental, gastric antral, ileocolic as well as colon free flaps have been described; however, by far the most common visceral reconstruction is a free jejunal reconstruction.^{12,16–25}

The earliest significant clinical series of microsurgical jejunal reconstructions were those reported by Jurkiewicz.^{26,27} But his daring and technical skill were not widely adopted for almost a further 20 years. The free jejunal flap, whether as a tube or patch, has since become one of the two most reliable reconstructive tools for laryngo-pharyngectomy and/or cervical oesophagus reconstruction.²⁸

Tubed or patch fasciocutaneous flaps are the other main alternative reconstructive options for pharyngeal defects. The most common flaps used are the anterolateral thigh and radial forearm flaps.^{29–33}

Assessment and planning

As with any operative surgery, planning remains the most important step in execution of the technique. This is best considered as part of a regular multidisciplinary meeting, which includes, in addition to head and neck, oral maxillofacial and plastic surgeons, radiation oncologists, medical oncologists, pathologists, speech therapists, dieticians, physiotherapists, social workers as well as a radiologist specializing in head and neck malignancies. An estimation of the extent of the defect and the need for reconstruction is discussed at these meetings. The reconstructive team, in conjunction with the ablative team, can decide on the best reconstructive option and begin planning for surgery after assessment of all possible donor sites. Previous history of laparotomy and upper GI surgery is noted and the patient's forearms and thighs are assessed.

A decision is also made at these multidisciplinary meetings in relation to the need for peri-operative radiotherapy and preoperative dental surgery, as well as nutritional needs. Most, if not all patients requiring major reconstruction have either advanced disease or chemo-radiation failure for relatively advanced disease and suffer from malnutrition. The need for nutritional supplementation is almost universal, including during the radiation therapy period. This may require percutaneous endoscopic gastric (PEG) tube insertion, depending on the surgical unit. Nutritional status will influence wound healing and reduce fistula formation. Uncomplicated healing streamlines the programming of radiation therapy in the shortest time window possible for the best therapeutic outcome.

Reconstruction

The broad principles of pharyngeal reconstruction are:

- maintaining or recreating a patent airway and protection from aspiration;
- re-establishing the integrity of the pharyngeal pathway to allow swallowing and adequate caloric intake; and
- voice and speech rehabilitation.

All of these endeavours have in common the creation of a patent tube. Salvage of all these functions is possible to various extents. The advent of microsurgery has made possible transfer of large amounts of tissue sculpted to more or less reconstruct the created defect. In addition, introduction of tissues with a new vascular supply into settings of advanced disease requiring major resections and radiotherapy or following chemo-radiation failure, promotes better wound healing and discourages fistula formation.

The two key determinants that influence the nature of the reconstruction are: the *surgery* (i.e. the defect created as well as donor availabilities) and the *patient's general status*. Many of these patients have life long history of heavy smoking and drinking, with the attendant risk of cardiac or respiratory disease and malnourishment. These are all factors to be considered in the light of the length of surgery and the added morbidity

from choice of donor sites. The added burden of a laparotomy or a chest flap on the respiratory reserves, the speed of skin flaps versus bowel in patients with poor cardiac reserve or malnourishment and the benefits of donor sites that allow simultaneous access during the primary resection for two-team surgery are issues to ponder. Preoperative anaesthetic, respiratory and cardiac assessment is mandatory. Any reasonable optimization of the patient's status should be undertaken prior to surgery.

All patients require confirmation of continuity and integrity of the UAD tract at 7–10 days postoperatively, with a contrast study before removal of nasogastric tubes and resumption of oral intake.

Reconstructive options

Local flaps

In practical terms, these include surrounding cervical skin and soft tissue and they rarely provide a practical reconstructive option for major defects. Not only is the neck skin vasculature unreliable, especially after flap elevation and block dissection, but it is generally sacrosanct to ensure cover of vital structures such as the carotid vessels. Frequently the neck skin has been or will be irradiated. The generalized devascularization associated with the treatment modalities greatly favours the importation of new, independently vascularized tissue, either from a regional source or more commonly now as a free flap transfer. Recently, the supraclavicular flap based on the transverse cervical vessels including a deltoid skin extension has been successfully used in lower level pharyngeal reconstructions.

Regional flaps

Pectoralis major

This type V Mathes and Nahai myocutaneous flap remains one of the most reliable reconstructive options for the head and neck.⁴ With the advent of microsurgical reconstructions it has been increasingly relegated to a second choice or salvage reconstructive option. Some of the current indications for its use include:

- situations where general patient state and systemic disease dictate reduced operative time;
- in combination with another flap or alone, where an external skin defect is present or has evolved after primary surgery;
- in coverage and protection of major neck vessels;
- in closure of pharyngostome; and
- wound dehiscence.

This flap is based on the pectoral branch of the acromiothoracic axis. It is most commonly raised as a myocutaneous flap with its skin island placed medially in women to reduce breast tissue inclusion. The skin component is rolled to form a tube to reconstruct circumferential defects. In order to avoid traction on the vascular pedicle a 3 cm cuff of muscle should be retained at the clavicular origin where possible. A so-called defensive incision for accessing the muscle without violating the potential delto-pectoral

salvage flap is made and the flap is raised and, where possible, tunnelled through the neck into the defect. For partial defects the skin island can be designed as a patch and sutured into the remnant pharyngeal mucosa.

Anchoring the remnant pharynx and cervical oesophagus to the pre-vertebral fascia, interdigitating the lower flap inset with the oesophagus and de-epithelization of the leading skin edge have also been described as means of reducing stricture and fistula formation. Others have advocated removal of the skin island and using only the myofascial component of the flap for repair to reduce bulk and to discard the least vascularized tissue component.

Complications

The reduced operative time, avoidance of the complications and morbidity related to abdominal surgery as well as inherent risks with microsurgical flap procedures are often cited as clinical grounds for use of the pectoralis major flap as a primary reconstructive option. Koh *et al.* reported a comparison of the average operating times for the pectoralis major, 76 +7 min (54–105 min), and the free flap, 145 +11 min (115–205 min), components of reconstruction cases.³⁴

Complication risks for flaps in head and neck reconstruction overall include:^{35–42}

- total flap necrosis (0–2.7%)
- partial flap necrosis (4–29%)
- pharyngocutaneous fistula formation (5.5–29%)
- stricture formation (0–27.2%)
- wound dehiscence (2.8–26%)
- infection (2–24%)
- bleeding (1–7%).

Table 28.1 lists published outcome studies specific to pharyngeal reconstructions. Increased flap complication rates are reported

with hypopharyngeal reconstructions, female patients, previous radiation therapy, obesity, patients >70 years old and preoperative malnutrition (albumin <4.0 g/dL).^{37,39,43}

Flap bulk often precludes meaningful voice rehabilitation using a tracheoesophageal puncture (TEP). In addition, recurrent descent and obstruction of the stoma may require surgical revisions.

Miscellaneous

Other regional pedicled flaps described include gastric pull-up flap, the myocutaneous latissimus dorsi and trapezius flaps, as well as the traditional fasciocutaneous deltopectoral or its modification, the internal mammary artery perforator (IMAP) flap. This is essentially a paramedian vertically oriented propeller flap based on the 2nd or 2nd/3rd internal mammary perforators. It can be rotated 180° and employed for some hypopharyngeal reconstructions.

Free flaps

The most common arterial recipient vessel is the superior thyroid or facial and the most common veins are the internal and external jugular or facial veins. Free flap reconstructions are broadly divided into two groups: the *visceral free flaps*, the commonest being the jejunal transfer, and *fasciocutaneous free flaps*, from the radial forearm and anterolateral thigh.

Free jejunum

For obvious reasons, jejunum is an ideal reconstructive option for pharyngeal and upper oesophageal reconstructions. Previous laparotomy, although not absolute, is a relative contraindication to its use. Patients with minimal respiratory reserve should be considered with caution, given

Table 28.1 Pectoralis major and other myocutaneous flaps

the additional morbidity of a laparotomy. A segment of proximal jejunum up to 25 cm length can be transferred as a free flap. The luminal diameter of the jejunal flap ranges between 3 and 5 cm. Despite its advantages, this flap has several technical shortcomings:

- It is exquisitely sensitive to hypoxia, any hypoxia beyond 3 h will almost always result in flap death and subsequent potentially catastrophic fistula formations.^{50,51}
- The vein is particularly thin and will not tolerate traction.
- The pedicle remains relatively short in comparison to its fasciocutaneous counterparts; the average length is described as 4–6 cm with a maximum length of 10 cm based on superior mesenteric vascular axis.

An isolated segment of jejunum is measured under mild stretch to the length of the defect and is transferred in an isoperistaltic orientation. The loop is chosen as proximal to the duodenum as is feasible because here the mesenteric vessels are longest. The oropharyngeal inset can be technically difficult, not least due to usual size discrepancies. Either a slit in the anti-mesenteric border or closing suture of the oropharyngeal remnant may be used to readjust for size mismatches.

Island jejunal patches based on the same vascular arcade can be reoriented and inset into a split in the upper end of the tube to accommodate wide oropharyngeal discrepancies. A nasogastric tube is passed through the jejunal segment, and the tube length is adjusted and anchored at either end, such that the pedicle trails without tension into the recipient vessel site field. Definitive repair of each end awaits microvascular anastomosis so as to reduce ischaemic time. The lower inset is performed last.

All bowel anastomoses are done using interrupted sutures rather than staples or continuous sutures. Any significant redundancy in bowel length will increase the postoperative swallowing difficulties and a common error is to design the segment too long. A survey of the reported outcomes in the literature, outlined in the next section, supports its reliability and low complication rate (Figure 28.1).

Flap monitoring can be performed by visualizing the mesentery through a temporary window in the neck incision or externalization of a separate jejunal ring isolated separately on the same vascular arcade. High reconstructions may be visible through the mouth, otherwise by endoscopy.

Figure 28.1 (a, b, c, d, e) Jejunum harvest and inset with follow-up contrast swallow X-rays.

Complications related to free jejunum flaps

In addition to general medical morbidity and mortality related chiefly to cardiorespiratory embarrassment, flap-related complications include:

- total flap necrosis (0–13%)
- pharyngocutaneous fistula formation (0–22%)
- stricture formation (0–16%)
- abdominal complications (0–4.35%).^{44,46,47,52–56}

In a recent series of 368 consecutive pharyngeal reconstructions the authors compared their results with a meta-analysis of published free skin flaps. They show that the jejunum was superior in all parameters (pharyngocutaneous fistula (8.2% versus 18.7%), stricture formation (10.9% versus 17.9%) and resumption of oral diet (91.6% versus 90.7%).⁵⁶

Free skin flaps

Tubed anterolateral thigh flap

The anterolateral thigh (ALT) flap, originally described as a type B fasciocutaneous flap by Song and colleagues,⁵⁷ has been shown to be mostly a type C fasciocutaneous flap. The flap is based on the

descending branch of the lateral circumflex artery. Often multiple perforators are noted, which can be harvested after dissection through their intramuscular course.³¹ This is a robust flap with a very long pedicle. The typical head and neck cancer patient is male and has lost weight, both favourable characteristics for ALT flap usage. This makes it the preferred skin flap for pharyngeal reconstructions. Its fascial layer can be taken beyond the limits of the skin edge and permit a double layer repair without overlap of the suture lines, thereby reducing fistula and stricture formation. The long pedicle makes for easy anastomosis compared with bowel and the donor site can be closed directly. This flap has gained strong popularity in reconstruction of the hypopharynx⁵⁸ (Figure 28.2).

Tubed radial artery forearm flap

Assessment and operative planning for the radial artery flap starts preoperatively with confirmation of a favourable Allen's test. This confirms viable perfusion of the hand after ligation of the radial artery.

The radial forearm flap is a well-vascularized fasciocutaneous flap^{29,59–61} based on the radial artery and its venae comitan-

tes, a long, large-diameter pedicle that has ensured this flap's popularity. The subcutaneous venous tributaries can be taken as alternative or additional drainage. The perforating vessels penetrate the radial aspect of the thin septum separating the flexor carpi radialis (FCR) and brachioradialis tendons. The septocutaneous perforators are concentrated in the lower third of the forearm along the axis of the artery and the fascia lateral or medial to this cleft is not essential for its viability. As the flap vascularity is distal and the skin is favourably thinner distally, the flap design is correspondingly from this region. It should be noted that the forearm skin is less hairy on the ulnar side and the skin island is best harvested from this side, its vascular source being still adequate from the radial perforators carried via the fascial bridge. When the flap is designed distally it is necessary to trace the pedicle to the cubital fossa even if pedicle length is not an issue, as the venae comitantes are of very small diameter until almost the level of the cubital fossa.

Radial and ALT flap-related complications include:

- total flap failure (0–5%)
- pharyngocutaneous fistula (1–27%)
- stricture formation (2–30%)
- partial flap loss (0–5%).^{1,44,45,58,62–66}

Miscellaneous

Lateral arm, ulnar and even tensor fascia lata flaps have been described as fasciocutaneous options. Ileocolic segments using the ileocaecal valve, free colonic segments as well as gastro-omental flaps have also been described as visceral alternatives. These options represent third-line options and are beyond the scope of this text.

Voice

At its most basic, voice represents increasing complex manipulation of a fundamental tone, which finds its origin at the larynx, before passing through the chambers above and exiting as voice. Speech is conversion of this sound by the tongue, the soft and hard palates, lips, pharynx and teeth. The vocal folds open and close in rapid succession, allowing air to form periodic sound waves. The movement theory behind vocal fold function is called myoelastic aerodynamic theory.⁶⁷ In simple terms, as the pressure rises below the vocal folds, this pressure leads to release of the air and forces the vocal cords apart, thereby generating vibration. As the pressure drops momentarily the vocal folds fall back into their midline position and the cycle continues.

Voice rehabilitation devices

There are many forms of vocal rehabilitation, basically divided into *non-surgical* or *surgical*. The non-surgical means include the electrolarynx and pneumatic artificial larynx. Surgical methods of reconstruction are themselves divided into neoglottis, TEP and prosthesis, and visceral voice tube reconstruction.

Neoglottis

Using local tissues as flaps, a deliberate fistula is created between the trachea and the oesophagus. The problem with this method is that there is a high rate of regurgitation, aspiration as well as stenosis and fistula closure.

Tracheoesophageal puncture and prosthesis

In this method, a fistula is created between the posterior wall of the trachea and the oesophagus. A prosthetic device with a one-way valve is then placed across the fistula. By occluding the tracheal stoma air is forced through the fistula, vibrating sequentially up the oesophagus and being articulated into speech on leaving the mouth. The one-way valve prevents regurgitation of food from the oesophagus into the trachea. There are a variety of these prostheses on the market, including Blom-Singer, Provox and Nijdam devices.^{68–73} There is debate as to whether TEP should be performed primarily or secondarily, some arguing that the incidence of stricture formation is higher in a primary setting although other studies disagree.⁷⁴ Despite their inherent advantage in application and functional outcome there are a number of associated disadvantages, which include: dilatation of the TEP and associated aspiration and regurgitation, stenosis, uncommonly oesophageal perforation, colonization with fungus and bacteria, dislodgement of the prosthesis into the trachea leading to aspiration and obstruction from secretions and food particles. This TEP procedure can be performed between the posterior tracheal wall as well as the neo-oesophagus when constructed from pedicled or free tissue transfer.

Visceral voice tube reconstruction

Where a free jejunum or ileocolon is used, a segment of jejunum or ileum can be used as a voice chamber. These are uncommonly used. The jejunal segment or ileum is used as a conduit for air to be transferred into the neo-oesophagus and pharynx.^{16,75,76}

Complications and clinical outcomes: Study results

There are a large number of publications reporting functional outcomes, including swallowing, stricture and fistula formation, operative surgical outcomes such as flap failure, and medical complications as well as death, but there are no randomized trial studies comparing the various visceral and fasciocutaneous flap reconstructions. Many of the functional outcome measures are not consistent across the literature, making comparisons difficult. In general, it is thought the jejunal flap yields better swallowing with less chance of stricture, whereas fascio- or myocutaneous flaps, by the virtue of tubing inset and incisional closures, are more likely to stricture. The voice and thus speech quality associated with skin flaps, however, is thought to be superior to the wet quality of jejunum voice, but the evidence

is weak. One small series reports most of the speech parameters were inferior with the jejunal reconstructions.⁷⁷ In a longer term study of patients undergoing jejunal reconstructions, Sharp *et al.*⁷⁸ reported 73% of their series had no dysphonia and 89% had no or mild dysphagia.

In a large series, Deschler and colleagues reported a comparison between 919 jejunal flaps and 179 tubed forearm radial flaps. Flap losses were 7.5% versus 1.8%, whereas fistula and stenosis formation were 17% versus 23% and 9.1% versus 16%, respectively.⁷⁹ The best speech is achieved with a TEP, although tracheal, jejunal as well as ileal conduits have been reported, but remain uncommon.^{80,81} Other reports from data pooled from a large series of results suggest that the risk of stenosis or fistula formation is increased substantially with tubed fasciocutaneous radial forearm flaps when compared to jejunal reconstructions. In addition to the results discussed above, Tables 28.2 and 28.3 summarize some of the larger data series on pharyngeal reconstructions.⁸²

Management strategies for major flap complications

Pharyngocutaneous fistula

Fistulas are common complications of pharyngeal reconstructions. The literature, although varied, reflects a trend towards a higher rate in fasciocutaneous flaps, perhaps reflecting the additional seam suture line associated with tubing of the flaps, as well as, in pedicled flaps, the risk of tension on the most vital part of the flap. Various studies have sought to delineate specific predictive risk factors attributable to:

- tumour factor – extent of disease and extent of oncological resection; or
- patient factors – preoperative albumin, age, sex, weight, as well as radiation history among other parameters.

Flap type

A recent report looked at early postoperative indicators for fistula formation. Postoperative fever during the first 48 h,⁸⁷ atrial fibrillation and preoperative albumin could not be implicated. However, a persistent low postoperative albumin (as early as 3rd postoperative day) as well as elevated white cell count was shown to be an indicator of an early leak.⁸⁸

Most commonly, fistulas are managed conservatively, ideally directing drainage to the contralateral neck, away from the great vessels if a neck dissection has been performed. The great majority of small fistulas close spontaneously over the course of 1–2 weeks. Significant leaks will require judicious debridement of necrotic and infected tissues and importation of healthy vascularized tissue. Consideration of regional flaps such as pectoralis major, deltopectoral and latissimus dorsi are the likely best options.^{89–91} Clinical surveillance remains important as contrast studies may yield false-negative rates of up to 14%. Appropriate prophylactic antibiotics, antireflux medication⁹² (proton pump

inhibitors or ranitidine) and meticulous surgical technique and tension-free closure help reduce infection and fistula rates. Late fistulas during or after radiation therapy are relatively rare, but should be considered with any patient who presents with evidence of infection in the neck during the late postoperative period.

Flap failure

This is a serious setback for the patient and the surgeon. Luckily, with increased experience and better practices, failure rates continue to decline in major institutions. Monitoring is difficult but early recognition of flap compromise may enable revision of the anastomoses and salvage of the flap. This is possible with skin flaps but unlikely with bowel. Acceptance of failure and early debridement may allow immediate re-do reconstruction in the interests of obtaining healing in time for optimal scheduling of radiotherapy. But the wisdom of this secondary reconstruction is in part determined by the state of the patient as well as local cervical tissues. Where there is gross contamination and infection there is a real risk of repeat micro-surgical failure, and a regional flap reconstruction should generally be considered, after debridement, external fistula formation, salivary diversion and settling of infection. Onoda *et al.*,⁹³ however, with experience of over 600 free jejunal transfers at their unit, report use of an immediate second jejunal flap where the first flap has failed, allowing adjuvant therapy to proceed quickly. The most important clinical sign of a jejunal flap failure is per oral bleeding.⁹⁴

Stricture formation

Stricture formation, which may be related to flap type or postoperative radiation therapy, could lead to dysphagia. This is often treated with repeated endoscopic dilatations.

Future directions and tissue engineering

Current reconstructive techniques provide restoration of only the most primitive of functions. The great frontier for a reconstructive surgeon remains a nuanced reconstruction and return of function. Increasingly, tissue engineering is yielding promising results in regenerating various tissues and structural combinations. The three requirements are scaffold, cells and *in vivo* regulatory growth factors. Rudimentary tracheal reconstruction for tracheal stenosis has already been performed using a combination of Marlex and bovine collagen-based scaffold.⁹⁵

This is of course a long way away from reconstructing a functional larynx. Although still in its infancy, the future is pregnant with hope that one day *like tissue* can in fact be replaced with *like tissue*, as Sir Harold Gillies, the founder of the discipline of plastic surgery, had set in stone as the ultimate aim of restoration surgery.

CHAPTER 29

Skull base reconstruction

Ross D. Farhadieh^{1,2} and Wayne A.J. Morrison³

¹Panthea Plastic Surgery Clinics, Sydney & Canberra, Australia

²Australian National University, Canberra, Australia

³O'Brien Institute and Department of Surgery, University of Melbourne, Melbourne, Australia

Introduction

Management of skull base malignancies has over the years posed a challenge to both ablative and reconstructive surgeons. Surgical access, complete tumour extirpation, proximity and concentration of vital neurovascular structures traversing the surgical field have been tempered in equal measure by reconstructive needs for robust, watertight seal, dead space obliteration, while ideally providing adequate skeletal and soft tissue support for the defect.

Early reconstructive attempts were limited to skin grafts, which were often applied to bare dura or bone.^{1,2} Staged tubed pedicled flaps became a mainstay treatment, with temporalis muscle the only other local option for orbital reconstruction and other similar defects.^{3,4} The advent of a successful craniofacial surgical approach, development of axial flaps and free flaps, as well as increased accuracy of definition in imaging techniques have led to a steady improvement in survival and reconstructive outcomes.¹ Bakamjian, McGregor and Thompson described use of axial faciocutaneous flaps (deltopectoral and forehead flaps) for oropharyngeal and orbital reconstructions.^{5–7} The pectoralis major⁸ and latissimus dorsi⁹ myocutaneous flaps were stretched to their limits, transposed externally to the orbital level and middle cranial fossa, respectively.

The introduction of microsurgery brought about the tools and means to transfer well-vascularized tissue and bulk to large defects in all parts of the skull base. Sculpted to fit the defect, provide a watertight seal separating the cranial fossae from the external environment, free tissue transfer can also provide well-vascularized tissue to either an already irradiated field or one which may undergo postoperative radiotherapy.

Anatomy and classification

The extracranial part of the skull base includes sphenoidal sinus, nasoethmoid, nasopharynx including the pterygopalatine fossa, the infratemporal fossa as well as the orbital roof.

The floor of the anterior, middle and posterior fossae forms its intracranial surface. Multiple classifications based on reconstructive requirements as well as anatomic boundaries, pathologic process and disease spread have been devised. Jackson and Hide divided the region into anterior and posterior divisions. The posterior area being further subdivided into posterior–anterior, posterior–central and posterior–posterior based on reconstructive requirements.¹⁰

Irish and colleagues reviewed 77 skull base neoplasms and divided the region into three zones based on anatomical boundaries and tumour spread¹¹ (Figure 29.1).

- Zone I: All tumours arising from the sinuses, orbit, other anterior structures as well as those which arise from the clivus and extend posteriorly to foramen magnum are included in this zone. Resection of these tumours requires an anterior approach.
- Zone II: These tumours primarily arise in the region of the infratemporal and pterygopalatine fossae. They extend into the middle cranial fossa.
- Zone III: neoplasms from the lateral face, parotid gland, ear and the temporal bone are included in this group extending into the posterior cranial fossa.

Pathology

Pathology of skull base neoplasms is broadly divided into those infiltrating from outside the skull base inwards and those originating from internal structures. By far the most common of these infiltrating lesions are cutaneous malignancies, especially squamous cell carcinomas (SCCs), but including other pathologies, such as nasopharyngeal carcinomas, salivary glands and glomous tumours. Those originating from the inside include acoustic neuromas, schwannomas and meningiomas. Among the more unusual tumours are lymphomas and sarcomas. Tissue diagnosis is imperative as surgery may not be appropriate in all cases, such as lymphomas.

Figure 29.1 Skull base zones based on Irish and colleagues' review¹¹ of 77 patients with skull base neoplasms. From Irish *et al.* (1994).¹¹ Reproduced with permission of Lippincott Williams & Wilkins.

Principles of management

A multidisciplinary team including specialist radiologists, radiation oncologists, medical oncologists, pathologists, nutritionists, neurosurgeons, plastic as well as head and neck surgeons forms the successful approach to management of patients with base of skull neoplasms. Improvements in imaging including increased accuracy and utilization of MRIs have significantly improved preoperative resection and reconstructive plans. Precise tissue diagnosis, extent of local, regional and distant disease and the patient's general examination and medical history are considered by the team before a comprehensive oncologic and rehabilitation plan is put forward to the patient.

As with many classifications the aforementioned represent arbitrary dividing lines across disease type and anatomical terrains. The general principles of management, however, remain vital in considering individual cases. These include:

- adequate surgical access determined by site, size and type;
- oncologic clearance or palliative debulking;
- repair of dural defects where present, which may, depending on the neurosurgery approach, require a prophylactic spinal drain to reduce intraventricular pressure and reduce the risk of cerebrospinal fluid (CSF) leak;

- watertight seal of intracranial contents from the external environment of the nasopharynx to reduce the risk of ascending meningitis;
- provision of bulk and obliteration of dead space;
- introduction of newly vascularized tissue, particularly in the settings of salvage surgery post radiation therapy disease progression or need for postoperative radiotherapy considerations; and
- provision of skeletal support where possible and necessary.

Zone I: Anterior skull base

Surgical access depending on the tumour type, size and site often requires a combined craniofacial approach. A lateral rhinotomy or a maxillotomy may be combined with a bicoronal approach both for access and protection of vital structures such as the optic nerve under direct view.^{12,13} When access to the clivus is required, a combined Le Fort I osteotomy, midline mandubolotomy and palatal split is taken in order to protect all peripheral vital structures.

Primitive reconstructions using split skin grafts applied to bare dura or bone resulted in high complication rates, up to 50% CSF leak in some of Ketcham's original series.¹ Local flaps are mostly inadequate for the purposes of such reconstructions. Early options included forehead, glabellar, pericranial or combined galeal-pericranial flaps.^{7,14–18} The temporalis muscle flap is also an option. This type III Mathes and Nahai muscle is supplied via deep temporal arterial branches of the maxillary division of the external carotid artery. Medial transposition into zone I is limited in its arc of rotation, barely reaching the medial orbital wall. Its most distal and critically needed portion is vulnerable to vascular insufficiency. Furthermore, this muscle maybe devascularized in neck dissections with ligation of external carotid artery. Donor site morbidity and temporal hollowing are significant drawbacks.⁴

Although myocutaneous flaps have been superseded by free flap surgery, they still have a place in reconstructive algorithms, especially in salvage of previous failed surgery. However, all are restricted by their pedicle reach and risk of distal necrosis. Pectoralis major, latissimus dorsi as well as trapezius muscle are the chief pedicled myocutaneous flaps available.^{8,9,19–21} Free flaps not constrained by anatomical limitations of pedicle origin nor potential of distal tip vascular insufficiency offer the opportunity to sculpt tissues to the defect, provide robust vascularized tissue, encourage healing and reduce complication rates. Where the extent of the resection dictates and there is a need for replacement of skeletal support, vascularized bone is preferable and essential if the field has received radiotherapy. Options include use of the free fibular with flexor hallucis longus muscle, deep circumflex iliac crest, parascapular with bone, scapular with bone, latissimus dorsi with angle of scapula or serratus anterior with rib flaps. These flaps can provide muscle bulk for dead space obliteration as well as vascularized bone for structural support. Alternatively, orbital wall, maxillary and cranial vault defects may be reconstructed with titanium mesh, provided well-vascularized coverage can be assured.

Zone II

The middle cranial, infratemporal and pterygopalatine fossae, extending from the posterior wall of the orbit, form zone II. The vital contents traversing it include facial, vestibulocochlear, maxillary and mandibular divisions of the trigeminal nerves, along with branches of carotid artery, a veritable anatomical minefield. The most common neoplasms extending from the outside into the region are cutaneous or parotid-based tumours. Nasopharyngeal carcinomas, meningiomas as well as glomus tumours are the common tumours arising inside zone II. In their analysis of base-of-skull tumours leading to this classification system, Irish and colleagues noted poor prognosis of tumours in this zone.¹¹

The reconstructive requirements depend on the patient as well as the size of the defect. Early reconstructive attempts utilized local options such as lateral scalp rotation and temporalis flaps. Deltopectoral, often extended through a delay procedure, was the only regional option prior to the advent of myocutaneous pedicled flaps. Workhorse myocutaneous flaps include pectoralis major, latissimus dorsi and trapezius. Microsurgical options are by far the best option in this zone and allow a well-vascularized sculpted tissue bulk with reliable perfusion to be introduced into the defect. Rectus abdominis myocutaneous flap provides a large, well-vascularized flap for such reconstructive purposes, with an adequately long pedicle, but its skin component is often unfavourable and the donor site defect is potentially morbid. More recently the anterolateral thigh fasciocutaneous flap has become the favoured donor because it allows a two-team approach, simultaneous dissection, long pedicle, large skin component with often direct closure of the defect, and, where needed, a nerve component. When the two ends of the facial nerve are present, even where there is previous weakness. Iseli and colleagues reported some facial nerve recovery in 97% of patients at a median of 6.2 months post operatively.²² Another study reported some recovery in 75% after a median of 7.7 months post operatively.²³

Zone III

Zone III contents include posterior cranial fossa, internal carotid artery, internal jugular vein, glossopharyngeal, vagus, accessory and hypoglossal nerves. Although Jones *et al.* reported schwannomas and glomus tumours as the most common presenting neoplasm in zone III, our experience, like that of Irish *et al.*, was that SCCs form the majority of these malignancies.^{11,24} Where a neck dissection is undertaken there is a likely devascularization of local flaps, including the temporalis muscle. Depending on size and site, regional options such as latissimus dorsi or trapezius muscles maybe used, or microsurgical options including faciocutaneous or myocutaneous flaps. Considerations should be given to patient position for flap donor site to allow simultaneous surgery by the resecting and reconstructive teams.

Technical consideration

Flap inset and dural seal are particularly important parts of the reconstructive consideration, complicated by gravity pulling the flap away from the base of skull and the dural repair site. Fibrin glue at the dural-free flap interface strengthens the repair. Thought must be given to providing enough soft tissue support to completely obliterate the dead space, abutting the flap as closely as possible against the repair site; suspension of the flap against the skull base provides additional support. In zone I the facial and superficial temporal vessels are the best recipients; care must be taken with the superficial temporal vein, which is thin walled. Where these are not available, a longer pedicle is needed and upper neck vessels may be used. For zones II and III, neck vessels are the most common recipient. Given their anatomical site, these flaps are commonly buried, especially in zone I. Implantable dopplers may be used, or a monitoring paddle can be exteriorized. Monitoring the pedicle distal to the microanastomosis site with a hand-held doppler is reassuring but does not detect venous obstruction.

Increasingly, the anterolateral thigh flap is used for reconstruction. In addition to allowing a two-team approach, having a low donor site complication rate, providing a long vascular pedicle, this flap permits harvesting of muscle for tissue bulk where needed as well as lateral cutaneous nerve of thigh as a graft source where primary facial nerve reconstruction is undertaken.

Complications

In addition to the standard medical complications, early surgical complications are most often related to communication of the dural space with the aerodigestive tract. Dural exposure, CSF leakage (up to 7%), ascending meningitis and local infections are the main risks.^{23,25} Free flap losses have steadily decreased; large series have showed a decline from 4% to 1.9% as a result of technical refinements.^{23,26,27} The overall complication rates remain significant, ranging between 29% and 60%.^{27–29} A more recent series reports overall complication rates of 30%.²³ Increasingly, free flaps are utilized to treat these defects. Neligan and colleagues reported higher complication rates where pedicled flaps were utilized.²⁸

Long-term limitations of the reconstruction include facial asymmetry, deformity, diplopia, trismus and nasal obstruction. These are inherent to lack of bony support, flap tissue bulk as well as a sequelae of radiation fibrosis.²⁵ This is hardly surprising considering the gross imbalance in sophistication between the tissues resected and tissues, which are chosen to replace them. Head and neck reconstruction remains the one great frontier for imaginative advances to be made in reconstructive surgery.

Superior imaging, refined surgical techniques and better preoperative planning have made reconstruction of the skull base malignancies, once considered inoperable and dangerous, routine at major centres. Appropriate consideration has to be

given to access, oncologic resection, vital structures traversing the region and technical considerations necessary for an optimal reconstruction.

CHAPTER 30

Cheek reconstruction

Adam C. Gascoigne¹ and Ross D. Farhadieh^{2,3}

¹Department of Anatomy and Neuroscience, University of Melbourne, Australia

²Panthea Plastic Surgery Clinics, Sydney & Canberra, Australia

³Australian National University, Canberra, Australia

Introduction

Defects of the cheek pose a significant challenge for the reconstructive surgeon. It is a highly visible area that may easily be compared to the opposite side, highlighting any asymmetry. This is perhaps one area in plastic surgery where reconstructive principles and aesthetic ideals are intertwined inextricably. An advanced understanding of facial anatomy and relevant reconstructive techniques is essential in tailoring the best solutions to the defect.

Anatomy

The cheek is a region on the face bordered by the eye, nose, lips, chin, mandible and ear (Figure 30.1). Functionally, it is important for mastication, swallowing and speech.¹ Aesthetically, it was classically described by Menick as 'a relatively flat, expansive surface, except for the soft roundness of the nasolabial folds and the cheek prominences'.² In greater detail, it is bordered by infraorbital rim and zygomatic arch superiorly, the lower lid–cheek junction, nasofacial junction, nasolabial fold, marionette line and labio-mandibular crease medially, the mandible inferiorly, and the preauricular contours of the tragus and helix of the ear laterally.^{2–4}

Skeletal

The facial skeleton underlying the cheek includes the mandible, zygoma, and maxilla.

Layers

In general, the layers of soft tissue in the cheek correspond to the basic five layers found elsewhere in the body (Table 30.1). From superficial to deep, the layers are skin, or dermis, followed by a layer of dense subcutaneous fat which is separated into lobules enclosed by fibrous septa. The third layer, the superficial

musculoaponeurotic system, or SMAS, was first described in 1976 by Mitz and Peyronie.⁵ It is continuous with the frontalis muscle superiorly, and the platysma inferiorly. There is another, looser layer of fat, between this and the fifth layer, that of the periosteum or deep fascia, which is often absent in the face where the tissues do not overlie bone or skeletal muscle.⁶ It may be helpful to remember them by the widely taught 'SCALP' mnemonic, corresponding to skin, connective tissue, aponeurotic layer, loose connective tissue and periosteum. In areas of the face not overlying bone, different layers are encountered. For example, in the parotid region the parotid fascia corresponds to the deep fascia, which takes the place of the periosteum; and in the buccal subunit of the cheek, the innermost layer of the cheek is the buccal mucosa. The superficial layers are otherwise the same.

Retaining ligaments

Fascial structures provide an anchor between bone and skin and provide soft tissue contours throughout the body.⁸ The retaining ligaments of the face have been studied in some detail as they are of particular relevance for aesthetic plastic surgical procedures such as rhytidectomy. They are of less importance in cheek reconstruction, as they will often have been disrupted by the trauma or oncologic resection which results in the defect. Nevertheless, a working knowledge of the retaining ligaments is helpful for the reconstructive surgeon. These are referred to elsewhere in this book. Briefly, the retaining ligaments of the cheek were first examined by Furnas in 1989.⁹ He described groups of ligaments that remain essential to our understanding of the soft tissue structure of the cheek:^{10–14}

- tear trough ligament
- orbicularis retaining ligament
- zygomatic cutaneous ligaments (McGregor's patch)
- masseteric cutaneous ligaments
- mandibular cutaneous ligament
- platysma auricular ligament.

Figure 30.1 Borders of the cheek. It is outlined by the infraorbital rim and zygomatic arch superiorly (green line), the lower lid-cheek junction, nasofacial junction, nasolabial fold, and labiomandibular crease medially (yellow lines), the mandible inferiorly (red line), and the preauricular crease laterally (blue line). These ligaments provide dense connections between either bone or fascia and the overlying skin and help to create many of the creases of the face. In reconstruction, it may be necessary to disrupt intact retaining ligaments in order to gain sufficient mobilization of flaps, or to recreate the effect of the retaining ligaments using deep sutures to underlying structures.

Muscles

The majority of the muscles of the cheek are muscles of facial expression. They are embryologically derived from the second branchial arch and are supplied by the nerve of that arch: the

facial. The exception is masseter. As a muscle of mastication it is derived from the first branchial arch, and is supplied by the mandibular division of the trigeminal nerve.¹⁵ The muscles of the cheek are:

- orbicularis oculi
- levator labii superioris
- levator labii superioris alaeque nasi
- depressor anguli oris
- risorius
- zygomaticus major
- zygomaticus minor
- platysma
- levator anguli oris
- buccinator
- masseter.

Blood supply

Branches of the external carotid artery supply all the tissues of the cheek. The facial artery (previously the external maxillary) arises from the external carotid artery in the region of the carotid triangle, runs across the inferior margin of the mandible anterior to the insertion of masseter, where the pulse may be palpated, runs a course that is convex anteriorly across the cheek deep to the zygomaticus muscles and becomes the angular artery at the medial canthus. Its branches are the ascending palatine, tonsillar, submental, glandular, inferior labial, superior labial and lateral nasal. It is accompanied by the facial vein, which runs lateral to the artery. The angiosome of the facial artery includes the medial cheek.¹⁶ The infraorbital artery is a branch of the maxillary artery (itself a terminal branch of the external carotid). It branches from the first part of the maxillary artery in the infratemporal fossa, then runs through the infraorbital canal to emerge on the face from the infraorbital foramen, where it anastomoses with the facial artery. The infraorbital vein accompanies the artery in its course and is a tributary of the facial vein. The superficial temporal artery runs upward within the substance of the parotid gland between the TMJ and the external acoustic meatus over the posterior zygomatic arch. It gives off two branches in the cheek: the transverse facial artery and the zygomatico-orbital artery.

The parotid duct and the buccal branches of the facial nerve accompany the transverse facial artery, the angiosome of which comprises the parotid gland and lateral cheek.¹⁶ The zygomatico-orbital artery runs superior to the zygomatic arch in parallel with the transverse facial artery as far as the orbicularis oculi muscle. It is accompanied by the retromandibular vein, which is formed by the union of the superficial temporal and maxillary veins from the pterygoid plexus. It divides into anterior and posterior branches, the former joining the facial vein before emptying into the internal jugular vein, the latter forming the external jugular vein with the posterior auricular vein.^{15,17}

Lymphatics

The pattern of lymphatic drainage of the cheek roughly mirrors the venous system, and is chiefly to the submental, submandibular, and periauricular nodes.¹⁸

Nerves

When operating on the cheek, the anatomic structure of chief importance is the facial nerve. As the sole motor supply to the muscles of facial expression, any facial nerve injury can have significant and lasting effects on patients quality of life. After emerging from the stylomastoid foramen the facial nerve enters the parotid gland. From this point on the ramification pattern of the facial nerve is virtually infinitely variable. In general, upon emerging from the parotid it has frontal, temporal, buccal, mandibular and cervical branches, and various landmarks have been described for locating individual branches.^{19,20} Depth of facial nerve branches also varies according to the area of the cheek being examined and the presence of tissue spaces, though in general they are deep to the SMAS laterally before becoming more superficial to supply muscles of facial expression medially.

The skin of the cheek, and of the face in general, is supplied almost exclusively by branches of the fifth cranial nerve: the trigeminal. The sole exception is an area of skin overlying the parotid gland and the angle of the mandible, which is supplied by the great auricular nerve, a branch of the cervical plexus. The remainder of the cheek is supplied by branches of the lower two divisions of the trigeminal nerve. The maxillary division provides two branches to the skin of the cheek. The infraorbital nerve supplies the cheek immediately beneath the eyelid, while the zygomaticofacial nerve supplies an area over the zygoma just lateral to the eye. The infraorbital nerve may be blocked by infiltration of local anaesthetic around where it exits the infraorbital foramen, which is located below the medial third of the infraorbital margin. The mandibular division also provides two branches. The buccal nerve supplies an area beneath the zygoma, between the distribution of the infraorbital and great auricular nerves. The mental nerve emerges from the mental foramen in line with the second premolar tooth and supplies the lower lip and surrounding skin.¹⁵

Aesthetic subunits

The cheek may be divided into four subunits: medial, lateral, buccal and zygomatic (Figure 30.2).^{1,21} In some texts, infraorbital and parotidomasseteric subunits are described, which are roughly analogous to the medial and lateral subunits, respectively.²² The medial subunit, otherwise known as the midcheek, may be further divided into prezygomatic and infrazygomatic areas.²³

Management

As is the case throughout reconstructive plastic surgery, the approach to reconstructing a cheek defect should be individualized for the patient, considering their overall health, prognosis, and functional status. The defect should be examined and characterized, noting such features as defect site, size, shape and depth, in addition to wound condition and aetiology, and any associated injury, where relevant.² Clinical photography may be helpful as a record. General principles are helpful to bear in mind while planning and executing the reconstruction, and Menick²⁴ has provided the following useful guidelines for reconstruction of facial units, which may be applied to cheek reconstruction:

- 1 Rebuild or resurface entire units, do not fill defects.
- 2 Alter the wound in site, size, and outline to assist reconstruction.
- 3 Consider separate flaps for individual aesthetic units when reconstructing composite defects.
- 4 Replace like with like – select the best match for skin colour, texture, hair quality, and thickness.
- 5 Free flaps may be used to provide bulk, but local facial skin is preferred for aesthetic covering.
- 6 In composite defects including the nose, the lip or cheek should be repaired initially due to the possibility of distortion during healing.
- 7 Individualize the reconstruction to the defect, allow time for the defect to mature and to plan the repair.
- 8 During revisional procedures, use the contralateral normal as the template.
- 9 Consider use of cartilage and bone grafts where appropriate to recreate the underlying architecture.

It should be borne in mind that in the cheek the crucial element for a good aesthetic result is uniformity of skin colour and texture, rather than contour or outline.²⁴ For this reason, local and

regional flaps from adjacent units are generally preferred over grafting. Exceptions to this rule are in cases requiring total facial resurfacing, in which case a complete skin graft or complete flap are preferred to a combination of other techniques. Distant skin is a poor match for facial skin, but for some wounds (large, contaminated, irradiated) transfer of distant tissue using microvascular techniques is the only solution. In these situations a free flap may be used to provide mucosal lining and tissue build, with local and regional flaps mobilized secondarily to provide permanent external skin. For smaller defects that may be amenable to direct closure, scars should be placed either in the borders of aesthetic units or in parallel with relaxed skin tension lines (RSTLs), which are perpendicular to lines of maximum skin extensibility (Figure 30.3).²⁵

Techniques for reconstruction of cheek defects are as follows:

- secondary intention
- direct closure
- tissue expansion
- local flaps
- cervicofacial flaps
- regional flaps
- skin grafting
- free flaps
- prefabrication.

Figure 30.3 Relaxed skin tension lines (RSTLs) of the face. Source: Baker, 2007.²¹ Reproduced with permission of Elsevier.

All of these are useful in the management of defects of the cheek. However, as discussed above, nearby tissues provide the best colour and texture match for cheek skin, and as such local and cervicofacial flaps are generally preferred where the lesion is not amenable to direct closure. Use of each of these techniques in reconstruction of the cheek is discussed below.

Secondary intention

Wounds able to form granulation tissue may be allowed to heal by secondary intention following resection of tumour, or debridement of devitalized tissue following trauma. Defects less than 1 cm may produce an acceptable result when left to heal by secondary intention, however the aesthetic appearance is generally inferior to other approaches due to wound contraction.¹⁸ As such it is generally not appropriate for defects close to the eyelid, nose and lip due to the potential for distortion.⁴

Direct closure

The simplest means of reconstructing a cheek defect is direct closure. It has been suggested that defects of up to 4 cm in size are amenable to direct closure, and that this should be the technique of choice where scars may be concealed in borders of aesthetic units or in parallel with RSTLs.^{18,26} Prior to attempting direct closure, it is important to check that there is sufficient skin laxity to allow tension-free closure. Preoperative examination and intraoperative tailor-tacking may be of assistance in assessing this.³ Undermining of wound edges by up to 4 cm may allow further mobilization of wound edges to directly close defects which would otherwise be under excessive tension.¹⁸ Dog-ears should be excised at the time of initial closure, as it is widely perceived that the cheek is an area in which they are unlikely to settle with time.^{3,27} Areas where direct closure may be a particularly viable option include the perialar and preauricular areas. In both these areas, abundance of skin laxity and proximity to the border of the cheek may allow larger defects to be closed with a well-concealed scar, particularly with the aid of undermining.³

Tissue expansion

Tissue expansion is a useful adjunct for other means of managing a defect in the cheek. Internal or external tissue expanders may be used to increase available skin to enable a repair which would otherwise result in excessive wound tension.^{28,29} However, caution should be exercised to avoid injury or compression of branches of the facial or trigeminal nerves.²⁸ Furthermore, since weeks are required for useful tissue expansion, circumstances such as oncologic urgency may preclude its use in some cases.¹

Local flaps

The most robust and aesthetic means of reconstructing cheek defects not amenable to direct closure are local flaps such as advancement, rhomboid and bilobed flaps. The use of skin

from the same or adjacent aesthetic unit as the defect provides a good match for skin colour and texture, and wound contraction is not as significant an issue as with other methods of closure. Local flaps are of greatest usefulness in defects of the medial cheek, which has greater skin laxity than elsewhere in the face.²⁵ These have been described in detail earlier in this book.

Advancement

A simple advancement flap may be used to close wounds that are too large or where direct closure would result in excessive wound tension. The term is generally used to describe flaps that have a linear configuration, in which the flap is slid into the defect.³⁰ Excision of equalizing or Burow's triangles to lengthen the wound edge may prevent bunching up of tissues and the formation of dog-ears. Laterally based unipedicle and V-Y advancement flaps are particularly useful in the medial cheek, due to the relative mobility and elasticity of tissues.³⁰ Advancement is less useful in the lateral cheek due to the lesser amount of subcutaneous fat and denser connections to the underlying fascia via retaining ligaments.

Rhomboid

The rhomboid flap was developed by Limberg in Russia during the early twentieth century and first described in English in 1946.³¹ It is essentially a variety of random pattern transposition flap utilizing a flap shaped as an equilateral parallelogram (a rhombus).^{32–35} Advantages of the rhomboid flap include flexibility of arrangement, the surgeon being allowed to choose how to place the secondary defect to minimize wound tension and disguise the scar along RSTLs. The technique requires the excision of a rhombus of tissue with internal angles of 60 and 120° around the defect (Figure 30.4a). The flap is then created by making an incision approximately the length of the diameter of the defect outward from its midpoint, followed by a second incision of similar length at a 60° angle to the first.³⁴ The flap is then transposed into the defect. It should be noted that in general, the greatest degree of tension resulting from this method of closure is at the donor site, and that this method requires the excision of additional normal tissue to create the rhombus-shaped defect.³³ To address these problems, modifications of Limberg's original method have been described.

The Dufourmentel flap is one such modification (Figure 30.4b). It is more complex, but allows the surgeon to create a rhombus-shaped defect without being constricted by the original technique's requirement for 60 and 120° internal angles. As for the Limberg flap, the defect is excised in an equilateral parallelogram of tissue. However, the angles may be customized to minimize the amount of normal tissue excised. Lines are then drawn extending from the short diagonal and the midpoint of the defect (see Figure 30.4b). The incision is then made midway between these two lines for a length approximating the length of the sides of the defect. The second inci-

sion is then made for a similar length in the direction of the long axis of the defect. The resulting flap is transposed into the defect.^{32–34}

The Webster flap is a further modification of the Limberg flap (Figure 30.4c). Its design is similar to that of the Dufourmentel flap, but it utilizes an acutely angled W-plasty at the base of the flap to limit the length of the excision and preserve skin.³² Disadvantages of the Webster modification are the increased possibility of contracture, and the additional limb of resulting scar. Other variations on the rhomboid flap include the use of a circular incision and a curved flap³⁶ and the use of bilateral flaps to reconstruct larger defects.³⁷

Bilobed

The bilobed flap was developed by Esser in 1918 and described in English by Zimany in 1953.³⁸ Like the rhombic flap, it is a random pattern transposition flap. It consists of two lobes based on a single pedicle that allows the surgeon to utilize nearby tissue that is not immediately adjacent to the defect.^{34,39} It is most useful for reconstructing defects of the lower one third of the nose, but may be helpful for medium-sized cheek defects. It is also a useful alternative to a larger cervicofacial flap for large cheek defects.³⁹ In Essen's original design, each lobe was the same size as the defect and was rotated 90°. This tended to result in the formation of dog-ears at wound edges and the risk of pincushioning (also known as trapdoor deformity) of the lobes of the flap. To prevent these undesirable aesthetic outcomes, Zitelli described the modified bilobed flap in 1989.³⁸

The first lobe of the modified bilobed flap is placed immediately adjacent but at an angle to the defect, and the second next to the first at a similar angle. The first lobe should be designed slightly smaller than the defect, and the second lobe smaller again. Prior to making the incision it is important to ensure that the donor site for the second lobe can be closed primarily – a pinch test may be helpful in confirming this.³⁹ Once this is done, the first lobe is transposed into the defect, and the second lobe into the secondary defect left by the first lobe. Any resulting dog-ears should be dealt with at the time of the initial operation by excision of an equalizing triangle.

Cervicofacial flaps

The cervicofacial flap, developed from the cheek advancement flaps of Mustardé,⁴⁰ have become the method of choice to reconstruct facial defects that are too large for a local flap. They are the preferred method for even medium-sized defects (larger than 2 cm) for some authors, who find that local flaps result in an aesthetically displeasing scar.³ They are a combination rotation/advancement flap that make use of cervical skin, which provides a good match for facial skin colour, texture and thickness.³ They are useful for large defects of both the lateral cheek, where there is relatively less skin laxity,²⁵ and the medial cheek, where the scar may be con-

Figure 30.4 Main subtypes of rhomboid pattern flap. (a) Rhomboid flap, (b) Dufourmentel flap, (c) Webster flap. Source: Chu and Byrne, 2009.³⁴ Reproduced with permission of Elsevier.

cealed along the borders of the cheek. Cervicofacial flaps may be anteriorly or posteriorly based depending on the position of the defect and the direction of advancement of the flap. Posteriorly based cervicofacial flaps have a more robust blood supply than anteriorly based flaps due to preservation of the transverse branches of the facial and superficial temporal arteries.²⁷

The incision should follow the borders of the cheek where practical, and extend down onto the neck either anteriorly or

posteriorly depending on the decision of where to base the flap (Figures 30.5 and 30.6). In anteriorly based flaps, the incision follows the superior border of the cheek, the preauricular crease, around the ear toward the occipital hairline, before being extended inferiorly for as far as is necessary to mobilize sufficient tissue prior to back-cutting.¹ For larger defects or those extending into the neck, the incision may be extended inferiorly, creating a cervicothoracic flap.³⁴ For a posteriorly based flap, the incision follows the nasolabial crease and extends onto the

upper neck.⁴¹ Flaps extending to the posterior neck should be kept posterior to the anterior border of trapezius to avoid webbing of the scar.²⁷

Following the incision, the flap must be dissected in order to mobilize it into position. The dissection may be either subcutaneous or in a deeper plane. The deep plane cervicofacial flap (DPCFF) is based on the technique of the sub-SMAS facelift technique,⁴¹ designed to include cutaneous perforators of the facial artery in the case of anteriorly based flaps, or of the superficial temporal artery in posteriorly based flaps. Advocates of the deep plane approach praise its more robust blood supply, allowing more mobility of the flap, and the greater thickness of the flap providing a more aesthetically pleasing contour.^{41,42} Opponents of this approach suggest deep plane dissections are more difficult, with a greater risk of facial nerve injury and a greater risk of ectropion due to the increased weight of the flap.^{3,43} Published rates of flap necrosis are similar for subcutaneous and deep plane approaches.^{41,43} However, there is widespread agreement that the deep plane approach is preferred in patients in whom blood supply to the flap is a significant concern, such as patients with diabetes, smokers or those who have undergone radiotherapy to the area. The senior author's preference is to dissect only in the subcutaneous layer above the zygomatic cheek and overlying the parotid, and in the sub-SMAS plane below.

Regardless of the plane is chosen, the dissection should be extended into the temporal region to create sufficient laxity to prevent tension from the weight of the flap, which may result in ectropion.³ Periosteal suspension sutures may also be used to anchor the leading edge of the flap at the cheek/eyelid junction.^{1,44} Care should be taken during dissection to avoid injury to the branches of the facial nerve, particularly immediately anterior to the parotid where the branches are no longer protected by intervening parotid tissue.⁴² The cutaneous branches of the cervical plexus and mandibular

division of the trigeminal nerve should also be protected. Following dissection, the flap is advanced into the defect and sutured into place.

Regional flaps

For patients with large defects of the cheek in whom cervicofacial flaps are not viable, regional flaps are a robust option. Flaps to consider include the supraclavicular and deltopectoral flaps. The supraclavicular flap is an axial pattern flap based on the supraclavicular artery, which originates from the transverse cervical. After raising the flap, it may be tunnelled subcutaneously to reach the cheek, though care should be taken to avoid pressure on the pedicle. The deltopectoral is supplied by perforators from the internal mammary artery, though the distal part is supplied by branches of the thoracoacromial trunk which are cut during raising of the flap. For this reason a delay prior to transfer of the flap is required to ensure adequate vascularization of the distal part of the flap.⁴⁵

Skin grafting

Use of skin grafts to close a cheek defect is not preferred, as they generally provide a poor match for colour and skin texture of facial skin. Furthermore, secondary contracture may result in distortion which may not be desired, especially in proximity to eyelid, nose and lip.¹ Nevertheless, there is a place for skin grafting for patients with large defects not amenable to direct closure or a local flap, and in whom a more complex reconstruction may not be practical, such as the elderly or those with significant comorbidities. Full-thickness skin grafts are generally preferred as they are less likely to contract and have a better match for colour, texture and thickness. Common donor sites for facial defects are the preauricular and supraclavicular areas, and the nasolabial fold.⁴⁶ Due to their disadvantages, split-thickness skin grafts are generally only

used for temporary coverage while a definitive reconstruction is being planned, or in situations where oncologic recurrence is a possibility.

Free flaps

The most advanced option for reconstruction of very large defects, or in patients in whom other reconstructive options are not viable, is free tissue transfer. Suitable flaps include the radial forearm flap⁴⁷ and anterolateral thigh flap;⁴⁸ for patients requiring a bony element to their reconstruction, the osteocutaneous free fibular flap is particularly useful for reconstructing mandible.⁴⁹ Myocutaneous flaps based on rectus abdominis or latissimus dorsi may also be useful, though their use may result in a bulky reconstruction requiring significant revision.

Prefabrication

The complexity of soft tissue defects of the face has resulted in some novel techniques being developed. Two such techniques are prefabrication and prelamination. Pribaz has written extensively about the use of prefabricated and prelaminated flaps in head and neck reconstruction.^{50–52} He has defined prefabrication as the ‘pre-transfer implantation of a non-native vascular pedicle into tissue desired for reconstruction’, while prelamination describes the ‘pre-transfer implantation of anything else’.⁵² Thus prefabrication is a technique allowing the transfer of otherwise non-transferable tissue, and prelamination is the assembly of different types of tissue to reconstruct a composite defect prior to transfer. The technique of prefabrication has been named the ‘crane principle’, as the implanted pedicle acts as a ‘vascular crane’, a contrivance for lifting tissues from one

Table 30.2 Complications of cheek reconstruction

Surgical	Wound complications

Functional	Oral incompetence
	Eyelid ectropion
Aesthetic	Loss of symmetry
	Loss of skin quality
	Abnormal hair distribution

location to another.⁵¹ One disadvantage of these techniques is the prolonged period required for the reconstruction: by their nature they require at least two and perhaps several staged procedures. However, it is a technique that may be helpful where simpler alternatives are not viable, as in extensive burns or trauma.⁴⁵

Complications

Complications of cheek reconstruction may be divided into surgical, functional, and aesthetic complications (Table 30.2). Surgical complications include wound complications such as breakdown and infection and flap necrosis, which may be subdivided into superficial, partial and total necrosis according to the area of tissue involved. It is generally acknowledged that the rate of surgical complications is vastly increased in smokers or those with vascular disease.^{3,53} Functional complications, such as oral incompetence and lower eyelid ectropion, result from displacement of the angle of the mouth or the lateral canthus due to excessive flap tension, swelling or weight. These complications

may be avoided by careful flap design and the use of strategically placed deep sutures to fix the flap to underlying structures.² Finally, aesthetic complications such as loss of symmetry, loss of skin quality and abnormal hair distribution generally result from inappropriate selection of tissue used for the reconstruction. Revisional procedures may be required to improve the final result.

Contour defects

Some patients may present with a complex deformity resulting from a condition causing widespread facial atrophy. Since the predominant contour of the cheek is that of a smooth convex surface, this has a significant effect on facial appearance, producing obvious asymmetry when unilateral, or a 'starved' appearance when bilateral.^{54–56} The eponymous names for the unilateral and bilateral syndromes are Parry–Romberg^{57,58} and Barraquer–Simons,^{55,59} respectively. These have been described previously in this compendium. A number of techniques may be used in the treatment of widespread facial atrophy. These include the use of autologous tissue, as in fat grafting⁶⁰ or free flap surgery,^{54,55} or synthetic material such as filler and bone graft substitute.^{56,61} Synthetic fillers that have been used for hemifacial atrophy include biodegradable materials such as hyaluronic acid gel, and non-biodegradable materials such as silicone.^{62,63} However, due to concerns regarding long-term complications, use of silicone for treatment of facial atrophy has fallen out of favour.^{57,64}

It is essential to recognize the existence of two distinct problems underlying the deformity in facial atrophy: a paucity of soft tissue volume and an abnormal bony contour. Frequently, reconstruction of the bony contour by will be required in addition to restoration of soft tissue volume.⁶⁵ A variety of free flaps have been used for soft tissue restoration in facial atrophy, including omentum,⁶⁶ transverse rectus abdominis myocutaneous (TRAM),⁶⁷ scapular and parascapular⁶⁸ and groin flaps,⁶⁹ to name a few. Ultimately, the choice of technique will be determined by the degree of atrophy and the volume of tissue required, and risk of morbidity associated with the chosen reconstruction compared with the effect of the deformity on the patient's quality of life.

Conclusion

The approach to reconstructing a cheek defect should be tailored to the individual patient. Assessment of the patient's overall health, in addition to the characteristics of the defect, is essential in order to select an appropriate reconstructive technique. Detailed understanding of the facial anatomy and aesthetics are vital to the creation and execution of a sound plan. Taking these basic principles into consideration allows the surgeon to achieve harmonious aesthetic and functional results in reconstructing the full range of cheek defects.

CHAPTER 31

Lip reconstruction

Marlene S. See, Andrew N. Morritt and Navid Jallali

Department of Plastic Surgery, Charing Cross Hospital, London, UK

The lips constitute the main feature of the lower third of the face, and have been a focus of interest by reconstructive, cleft and aesthetic surgeons. Functionally, the lips play many important roles – articulation and enunciation in speech, maintenance of oral competence during eating, drinking and forceful blowing, and expression of emotion and kissing. These roles are possible because, unlike the other elements of the face, the lips are dynamic and mobile. Aesthetically, the vermillion is the hallmark. Reconstruction of the lips, therefore, aims to maintain these characteristics both for function and appearance. This chapter reviews the anatomy of the lips and presents an algorithm for reconstruction.

Anatomy

Embryology

The upper lip is derived from two distinct structures, namely the paired maxillary and nasomedial processes. Fusion of these processes gives rise to the characteristic features of the upper lip, such as the philtral columns, philtral dimple, Cupid's bow and white roll. The lower lip is formed from fusion of the paired mandibular processes, which result in a less defined lower lip. The topographical landmarks of the lip are illustrated in Figure 31.1.

Musculature

The muscles that animate the lips are illustrated in Figure 31.2. The principal muscle is the orbicularis oris, which forms a complex sphincter muscle. This muscle arises both from intrinsic fibres of the lip and from other muscles that insert into the lip. The deep and oblique fibres of orbicularis oris approximate the lips to the alveolar arch, while the superficial fibres purse and protrude the lips. The orbicularis oris can be dissected from its supportive muscles while preserving its viability, sensation and motor function, an important consideration in the choice of reconstruction.¹

Levator labii superioris elevate the upper lip, levator anguli oris and zygomaticus major draw the lateral upper lip up and back, while buccinator and risorius clear the gingival sulcus. The lower lip is depressed and retracted by the platysma, depressor anguli oris and depressor labii inferioris. The mentalis muscles cause elevation and protrusion of the central aspect of the lower lip. Loss of these muscles leads to lip incompetence and incisor show.

Vasculature

The blood supply to the upper and lower lips is the superior and inferior labial arteries respectively. These originate from the facial artery from either side of the face. The average distance of the superior labial artery from the oral commissure (as it branches off the facial artery) is 12 mm, and can be found along its course within 10 mm from the inferior border of the lips. However, the anatomy of the labial arteries can be variable. Magden *et al.* reported that 29% of superior labial arteries have a unilateral origin.³ This finding has important implications when raising pedicled flaps such as the Abbe or Estlander flaps. The superior labial artery has a mean diameter of between 1 and 2 mm at its origin, and is therefore large enough for microsurgical anastomosis.^{4,5} There are numerous reports and case series of lip replantation in the literature, and problems attributed to replantation are mainly related to the venous drainage of the replanted tissue.

The origin of the inferior labial artery varies between the lower margin of the mandible and the oral commissure.

Lymphatic drainage

The lymphatic drainage of the lips is ipsilaterally into the submental, submandibular and parotid nodes. Tissues in the midline drain bilaterally. Submental lymph nodes then drain into ipsilateral submandibular nodes. Submandibular and parotid nodes secondarily drain into the ipsilateral jugulodigastric lymph nodes.

Innervation

The facial nerve (VIIth cranial nerve) provides the motor innervation to the perioral musculature via its buccal and marginal mandibular branches. There are interconnections between both branches of the facial nerve distal to the parotid gland. The motor nerves are located on the undersurface of all the perioral musculature except for buccinator, levator anguli oris and mentalis, where the nerve lies on the superficial surface of these muscles.

The maxillary and mandibular branches of the trigeminal nerve (Vth cranial nerve) provide sensory innervation to the perioral region. Specifically, the infraorbital nerve, which is a terminal branch of the maxillary nerve, innervates the upper lip. The infraorbital foramen faces downward and medial and lies 4–7 mm below the infraorbital rim, on a vertical line that descends from the medial limbus of the iris. The nerve runs beneath the levator labii superioris and superficial to the levator anguli oris to supply the lateral nasal sidewall, ala, columella, medial cheek and upper lip. The lower lip, down to the labio-mental fold, is innervated by the mental nerve, which originates from the inferior alveolar nerve, a branch of the mandibular nerve. The mental foramen is located below the apex of the second mandibular bicuspid with 6–10 mm of lateral variability.

Figure 31.1 Topographical anatomy of the lips.

Figure 31.2 Lip musculature.

Anaesthesia

Surgical procedures to the perioral region should be preceded by a regional block, followed by local infiltration to the affected area for the adrenaline-facilitated vasoconstriction. Prior to local infiltration of the lip tissue, it is important to mark or tattoo the white roll of the lip either side of the planned resection in order to match this up afterwards. Any local infiltration, particularly with adrenaline, will obliterate the white roll. A 1 mm discrepancy between the vermillion and skin is noticeable at conversational distance.

The entire upper lip can be anaesthetized by bilateral infraorbital nerve block. This can be carried out either percutaneously or transorally.⁶ A 25- to 27-gauge needle is used and does not need to pass into the foramen to desensitize the lip. For the percutaneous route, the needle is placed medial to the nasolabial fold but lateral to the alar base. For the transoral route, the needle is passed transmucosally above the canine eminence.

The lower lip is anaesthetized by bilateral mental nerve blockade. This is performed intraorally by rolling the lower lip outward and stretching the mucosa to visualize the mental nerve just below the mucosa at the canine root. If the nerve is not readily visible, the surgeon should infiltrate local anaesthetic into the submucosa at the apices of the canines into the lower lateral buccal sulcus.

Goals of reconstruction

The three main goals of lip reconstruction are:

- preservation of oral continence – this requires a muscular integrity, normal sensation and an adequate oral aperture;
- preservation of function for speech and ingestion of food: and
- cosmesis.

Aetiology of lip defects

The commonest indication for lip reconstruction is following tumour extirpation. The lower lip is much more frequently affected by neoplasia compared to the upper lip, presumably due to greater actinic exposure. The vast majority of skin cancers are squamous cell carcinoma in origin and are more frequently encountered in males (2.4 times) as a result of greater sun exposure, alcohol and tobacco.⁷ Fortunately, these lesions often involve the area between the midline and the oral commissure, avoiding the need for commissural reconstruction. Other causes of lip defects include trauma, infection (e.g. noma), vasculitis and congenital causes such as vascular malformation or clefts.

Analysis of the defect

Before embarking on lip reconstruction, the site, size, depth and involvement of commissure all need to be contemplated.

Site

The upper lip has more topographical landmarks than the lower lip. The lower lip, lacking in features, is theoretically more expendable as donor tissue for reconstruction. However, functionally and socially, the lower lip deserves more consideration. The lower lip serves to maintain oral competence by containing solids and liquids within the oral cavity. Therefore, any reduction in sulcus depth, compounded by loss of sensation and poor muscle function will result in liquids leaking out of the mouth.

Hence, the surgeon needs to deliberate carefully in the following situations: when using lower lip tissue to reconstruct the upper lip, denervating the lower lip during the raising of local flaps, or the use of insensate and non-functional tissue such as the nasolabial or cheek tissue to reconstruct the lower lip.

Size

Although the absolute size of the tumour and excision margins is important, the percentage of the lip that has been ablated is crucial in deciding the reconstructive option. As previously mentioned, the lower lip is more expendable, especially in elderly patients with more laxity in the tissues, thereby permitting transposition, advancement or rotation flaps more readily. However, it is vital not to leave the patient with a microstomia. Although amenable to stretching, microstomia does result in imminent problems with dental care, insertion and removal of dentures.

Depth

The four layers of the lip from the oral cavity outwards are mucosa, muscle, vermillion and skin. With regard to the depth of the defect, the surgeon should 'replace like with like' and consider the reconstructive options accordingly.

Involvement of commissure

If the lip defect involves the oral commissure, then effort must be made to reconstruct the commissure as this is an important aesthetic landmark of the lips and face.

Algorithm for reconstruction

Vermillion defects

The vermillion is a unique feature of the lip. The vermillion is the transition zone between the stratified keratinized squamous epithelium of the skin and the non-keratinized squamous epithelium of the oral mucosa. This exists only in humans, and is the partially keratinized layer, which is red due to the reflection of the underlying blood vessels. The wet and dry vermillions are distinct; the dry vermillion tends to take on lipstick more readily.

For small lesions confined within the vermillion, the lesion should be excised as a vertical ellipse and sutured directly, avoiding extension of the incision onto the skin. This technique can also be employed for notch or whistle deformities of the lip, with the addition of a Z-plasty to avoid recurrence.

Large superficial defects confined to the vermillion can be left to heal by secondary intention, and tend to heal within 3–4 weeks with a good cosmetic result.

For full-thickness defects resulting in a deficiency of less than 50% of the total vermillion, the options include the axial musculo-vermillion advancement flap described by Goldstein⁸ or musculo-mucosal V to Y advancement flaps.⁹ For the axial musculo-vermillion advancement flap, the position of the labial artery is identified from the resection of the lesion and the flap is elevated deep to the labial artery, and then advanced into the defect (Figure 31.3). Although cross-lip flaps for vermillion reconstruction have been widely reported in the literature,^{10–12} it is our opinion that they should be avoided. Cross-lip flaps should not be undertaken lightly as they not only compromise the other intact lip, but also are difficult to tolerate as they are executed as a staged procedure with an intervening period of lip adhesion (i.e. the pedicle of the flap attached).

The facial artery myomucosal flap (FAMM) described by Pribaz *et al.* in 1992¹³ is a good option for vermillion defects of more than 50%. This flap can also be used for total vermillion reconstruction by raising bilateral flaps. The FAMM flap is a composite flap, which is raised from the lateral cheek, based on the facial artery as it courses though the cheek lateral to the buccinator muscle. It consists of mucosa, submucosa, a small amount of buccinator, a segment of the facial artery and venous plexus. It may be used as a superiorly based flap, which has retrograde perfusion via the angular artery, for the upper lip. Alternatively, the inferiorly based flap based on the facial artery is used for the lower lip. Wide flaps, up to the entire width of the cheek, and up to 7 or 8 cm in length, can be raised safely but the authors advocate thin flaps to reduce donor site morbidity (Figure 31.4).

Figure 31.3 The axial musculo-vermillion flap for full-thickness vermillion defects less than 50% of the total vermillion. The flap is elevated deep to the labial artery.

Figure 31.4 Illustrations of the superiorly based (left) and inferiorly based (right) facial artery myomucosal flaps (FAMM flaps) described by Pribaz. Source: Pribaz *et al.*, 1992.¹³ Reproduced with permission of Lippincott Williams & Wilkins.

Some patients undergo total vermillionectomy for severe actinic damage or unstable residual epithelium adjacent to a malignant lesion. In these cases of total vermillion deficiency, buccal mucosal advancement as a bipedicle flap described by Lustig *et al.*¹⁴ can be raised to resurface the defect. An incision is made in the buccal sulcus, and the bipedicle flap is advanced as a myomucosal flap including the labial artery. The donor site is left to heal by secondary intention (Figure 31.5).

Full-thickness lower lip defect

In addressing full-thickness defects of the lower lip, the rule of thirds provides an effective algorithm for reconstruction (Figure 31.6).

Defects less than 1/3 width

For defects up to a third of the total width of the lower lip, the edges of the defect can be approximated directly. It is important to carry out primary closure according to the layers; that is, the lining (buccal mucosa), the muscle and the cover (vermillion and skin). The buccal mucosa is sutured using an absorbable suture (e.g. polyglactin/Vicryl® or Vicryl Rapide®). The orbicularis oris muscle is also approximated with an absorbable suture (e.g. Vicryl, Monocryl® or PDS®/polydioxanone). The vermillion is sutured using an absorbable suture such as Vicryl Rapide.

As previously mentioned, prior to infiltration of any local anaesthetic agent, the vermillion junction and/or the white roll must be carefully marked to facilitate accurate approximation of the edges. Techniques for marking the vermillion junction or the white roll include tattooing or placing a single suture at the

Figure 31.6 The rule of thirds as an algorithm for reconstruction of full-thickness lower lip defects.

corresponding points either side of the defect. In some elderly patients, defects between a third to half of the width of the lower lip can be approximated, primarily due to increased laxity and redundancy of the tissues with age (Figure 31.7), however, for the majority of patients, defects greater than a third in width require flap reconstruction to avoid microstomia.

Defects between 1/3 and 2/3 widths

Defects between a third and two thirds of the width of the lower lip will require reconstruction with a flap. For these defects, local flaps offer the best option. The three main choices are the Karapandzic flap, Abbe flap and Estlander flap.

The *Karapandzic flap*, first described in 1974,¹⁵ is a rotation-advancement flap, which re-establishes the circumoral sphincter. The Karapandzic flap contains skin, innervated orbicularis oris

and mucosa, and can be used to reconstruct both upper and lower lip defects (Figure 31.8). The key element in raising this flap is to translate the vertical height of the lip defect to the width of the flap. Curvilinear incisions are made through skin and muscle, releasing the muscle fibres and suspensory ligaments but preserving the superior and inferior labial arteries and buccal branches of the facial nerve. The mucosal incisions are more limited, placed in the buccal sulcus long enough simply to enable advancement of the musculocutaneous component of the flaps. In the superiorly based Karapandzic flaps for lower lip defects, the mucosal incisions should only extend up to the mental nerve at the canine root in order to preserve sensation to any residual lower lip tissue. Limited mucosal incisions also prevent effacement of the buccal sulcus, which can lead to salivary incompetence.

The Karapandzic flap should be the first choice of reconstruction for moderate-sized defects as it is innervated, dynamic and therefore functional. The main disadvantage of the Karapandzic flap is the potential risk of microstomia, and the need for surgical revision to deepen the buccal sulcus if it is effaced.

The *Abbe flap*, described in 1898,¹⁶ is a staged lip-switch flap which provides effective reconstruction of defects of up to two thirds of the width of the lip not involving the oral commissure. The Abbe flap is raised from the junction of the middle and lateral thirds of the opposite lip, with a flap of approximately half the width of the defect but equal in height. Prior to raising the flap, the vermilion border on either side of the incisions (i.e. four points) are carefully marked to enable accurate closure of the donor site and inset of the flap. The flap is pedicled on the corresponding labial artery; its location can be identified on the free edge of the flap as the artery can be palpated. The pedicle is divided between 14 and 21 days later (Figure 31.9).

The main advantage of the Abbe flap is the ability to replace the vertical height of the defect and import vermilion

Figure 31.7 Variation in wedge excision and primary closure of lower lip defects.

Figure 31.8 Schematic diagram of the Karapandzic flap. (a) The defect following tumour extirpation, note the height of the defect, x , is equivalent to the width of each flap. The mucosal incisions are more limited. (b) The flap raised, preserving the neurovascular bundles (*) to each flap. (c) The final appearance of the lips, with a smaller oral aperture.

tissue into the defect. However, the disadvantages include a period of lip adhesion, imbalance of the white roll and vermillion and the insensate segment of imported tissue. Furthermore, as previously mentioned, around a third of the population have a unilateral origin of the superior labial artery, which has implications on the pivot point of the flap (i.e. the pivot point should be more proximal where the calibre of the artery is larger).

The *Estlander flap*, described in 1872,¹⁷ is a single stage lip-switch flap for defects involving the oral commissure (Figure 31.10). The flap is based medially, and is rotated into the defect to reconstruct the commissure and lip. Similar to the Abbe flap, the flap is designed to be equal in height but half the width of the defect. The reconstructed oral commissure usually has an obtuse or blunted angle, and frequently requires revision by means of a commissuroplasty. This is described further below.

Figure 31.9 (a) Schematic diagram of the Abbe flap. The flap is raised at the junction of the middle and lateral thirds of the contralateral lip. The four points denoting the vermilion border either side of the incisions for the flap are marked. The width of the flap (x) is half that of the defect ($2x$), but the height of the flap (h) is equivalent to that of the defect. The flap pedicle containing the labial artery is left attached for 2–3 weeks before division. (b) Design of upper lip Abbe flap for recurrent squamous cell carcinoma following previous wedge resection. (c) Raised flap and nasolabial excisions at donor site. Figure 31.10 Schematic diagram illustrating the Estlander flap to reconstruct defects involving the oral commissure. The four points denoting the vermilion border either side of the incisions for the flap are marked. The width of the flap (x) is half that of the defect ($2x$), but the height of the flap (h) is equivalent to that of the defect. Note the blunted neo-commissure, which is common sequelae of this flap. This may require a commissuroplasty at a later stage.

Defects more than 2/3 width or total lip defect

Lower lip defects greater than two thirds of the total width can be addressed with local flaps in selected cases. The Karapandzic flap previously described can be used for defects up to 80% of the total width. The main advantage of this flap is that it is innervated and therefore dynamic. However, the disadvantage of the Karapandzic flaps is the resulting microstomia. Other local flaps, such as the Gillies fan, McGregor and Nakajima flaps, have been described for large defects of the lower lip but these flaps are largely obsolete in our practice. The Gillies fan flap distorts the oral commissure, the McGregor and Nakajima flaps reconstruct the lip but the muscle fibre direction is changed and a new vermilion is required.

The *Bernard flap*, described in 1853,¹⁸ with the Webster modification provides the best reconstructive local option for total lip defects. The original Bernard operation involves a triangular wedge excision of the whole lower lip. The incision is extended laterally from both oral commissures with full-thickness triangular excision at the nasolabial area to enable direct closure of the lower lip wedge (Figure 31.11). The Webster modification, described in 1960,¹⁹ employs the principles of:

- quadrilateral or rectangular resection;
- medial advancement of one or two cheek-lip flaps;
- excision of skin and subcutaneous tissue only for removal of tissue excess;
- minimal incisions through the muscle laterally;
- buccal mucosa flaps for vermilion replacement; and
- Z-plasties on all vertical suture lines.

Hence, the planning of the Bernard–Webster flap begins with the cheek advancement flaps. The length of each advancement flap is equivalent to half the length of the horizontal lip defect. Then, superior curvilinear incisions are made along the nasolabial fold, integrated into Burrow's triangles, to enable advancement of the horizontal cheek advancement flaps. Inferiorly, incisions are made along the labiomental fold, also incorporated into Burrow's triangles. These incisions are deepened through skin, subcutaneous tissue and muscle to the level of the mucosa. The mucosa is only incised medially to allow advancement of

the cheek tissue, preserving as much of the intraoral lining as possible. These medial incisions are also placed superior to the skin flap design to allow mucosa to be delivered anteriorly and everted to create the vermilion of the reconstructed lip. Finally, the medial edges of each flap are inset with a three-layer closure. There is a relative contraindication for this flap in patients who have had previous facial surgery, or neck dissections resulting in ligation of the facial artery, thus compromising the cutaneous circulation. The other disadvantages of this flap are the potential for microstomia, notching of the central lip and effacement of the buccal sulcus, leading to oral incompetence.

The other less favoured option for total lip reconstruction is free tissue transfer. Whenever possible, local tissue must be used to reconstruct the lips. However, this may not be possible due to the need to reconstruct composite defects involving the whole lip and adjacent regions such as the chin and cheeks, the lack of suitable local tissue as the result of previous surgery or radiotherapy, and finally the increasing proficiency of plastic surgeons in performing microsurgical reconstruction. Care and attention should be paid when deciding on the choice of free flap reconstruction. Factors to take into consideration include skin colour match, the volume required to fill the defect, the ability to contour the flap to fit the defect, and the feasibility of suspending the flap to prevent ptosis.

Surgeons have proposed a multitude of flaps for lower lip reconstruction. The list includes radial forearm, anterolateral thigh, parascapular, rectus abdominis²⁰ and lateral arm flaps. These flaps can either be used in isolation, in combination with another flap either locally based or free tissue transfer, or pre-lamination of a free flap. The radial forearm free flap is the most popular choice because it provides a good colour match, is thin and therefore can be easily folded, has a long pedicle, can be harvested simultaneously during the oncological resection of the lower lip or preparation of neck recipient vessels, and can be harvested with the palmaris longus tendon as a static sling to suspend the lower lip reconstruction (Figure 31.12).

When undertaking free flap reconstruction, the first step involves obtaining a template of the defect. The surgeon needs to

Figure 31.12 Total lower lip reconstruction with radial forearm free flap. The flap has been suspended over a palmaris longus graft which was secured to the zygomatic arches.

be aware that the defect usually appears larger than the actual size of the tissue lost. This is due to the pull of the perioral and facial mimetic muscles, which retract the edge of the defect laterally. Thus, it is important to place tension on the edges of the defect medially before obtaining the template. Once the free flap has been raised, inseting the flap is another crucial process. The tension of the flap needs to be taut enough to prevent ptosis leading to salivary incompetence, but not too tight resulting in compromise to flap perfusion. Attention must also be directed towards the depth of the gingivobuccal sulcus, ensuring adequate depth to prevent drooling. If a static sling is placed simultaneously to suspend the flap, the sling is attached to a relatively stable structure, and the senior author prefers the periosteum of the zygomatic arch. Some authors advocate attaching the sling to remnants of zygomaticus major muscle to obtain a measure of dynamic movement.

The disadvantage of free flap reconstruction is that both the tissue and sling can relax with time, leading to ptosis, and oral incompetence. Furthermore, the results are aesthetically inferior to local flaps.

Full-thickness upper lip defect

We previously alluded to the topographical difference between the upper and lower lips, and due consideration has to be given to the philtral columns and Cupid's bow when planning the reconstruction. In men, the hair-bearing area of the upper lip is a further confounding factor in choice of reconstruction.

Similar to the lower lip, the rule of thirds is also used for the upper lip. Figure 31.13 illustrates a useful algorithm for upper lip defects.

Defects less than 1/3 width

Upper lip defects that do not involve the vermillion can be reconstructed with a full-thickness skin graft or local flaps such as the nasolabial flap. In men, hair-bearing tissue from the temporal scalp^{21–23} provides a reconstructive option which restores the moustache.

Lateral defects located between the philtral columns and the oral commissures are closed directly as for the lower lip,

Figure 31.13 The rule of thirds is a useful algorithm for reconstruction of full-thickness defects of the upper lip. *FTSG = full-thickness skin graft

Figure 31.14 Schematic diagram illustrating the Webster's perialar crescentic advancement flaps. The hashed area denotes skin excision only.

ensuring accurate approximation of the white roll and vermilion border. Central defects involving the philtral columns and Cupid's bow are also closed directly, but a useful adjunct is Webster's perialar crescentic excision and bilateral cheek advancement flaps (Figure 31.14).

Defects between 1/3 to 2/3 widths

As for the lower lip, the Karapandzic flap remains the first choice for local flap reconstruction of the upper lip, as it is dynamic and innervated, thereby providing a functional reconstruction. The alternatives are the Abbe and Estlander flaps. The former is employed for central defects, and the latter for defects involving the oral commissure. The perialar crescentic excision is a useful adjunct for the Abbe flap in reconstructing central

defects, and can also aid in closure of lateral defects together with the Estlander flap (by means of a contralateral perialar crescentic excision).

Defects more than 2/3 width or total lip defect

The same algorithm as for the lower lip applies for the upper lip (i.e. the Karapandzic flap, Bernard-Webster flap or free tissue transfer).

Commissuroplasty

Commissuroplasty is indicated in patients with microstomia, or a blunted oral commissure following lip reconstruction with local flaps such as the Estlander or Karapandzic flaps.

Figure 31.15 Left commissuroplasty following an acid burn. The right had been previously released.

In these patients, wherever possible, the vermillion is utilized either as advancement or transposition flaps. If the vermillion is too small or inadequate, then the buccal mucosa is used instead or in combination. Several methods have been modified from Dieffenbach's approach in 1831,²⁴ whereby a triangular wedge of scar tissue is excised and superior, lateral and inferior mucosal flaps are advanced to resurface the corner of the mouth.

A popular contemporary method is *Converse's commissuroplasty*, described in 1959 (Figure 31.15).²⁵ A triangular area of skin is excised to accommodate the elongated commissure. The buccal mucosal flaps are designed as shown in Figure 31.14, incised and advanced to form the neo-vermillion.

Conclusion

Lip defects can be approached with a stepwise algorithm ranging from primary closure to free tissue transfer. This chapter has by no means provided a comprehensive catalogue of the reconstructive

options available. We have not explored the surgical techniques for congenital lip defects, such as cleft lips, craniofacial clefts, macrostomia or microstomia; nor have we elaborated on the indications and techniques of face transplantation. However, as surgeons, it is imperative we adhere to the basic principles of replacing like with like, and focus on both function and form for lip reconstruction.

CHAPTER 32

Nasal reconstruction

Jean-Brice Duron and Marc Revol

Department of Plastic Surgery, Hôpital Saint-Louis, Paris, France

Introduction

The social stigma of nasal amputation for the patient represents a huge challenge for the reconstructive surgeon to achieve the good results that are possible today. Totally different from modern technical exploits such as face transplants or supermicrosurgery, the majority of cases can be performed by general plastic surgeons without the need for specialist equipment and training. However, the key to success is preoperative examination and planning.

Through the ages, nasal reconstruction has followed a slow but regular improvement due to advances in technique (the first forehead flap was recorded in the *Sushruta Samitha* (500 BC)¹), and closer attention to detail. Thus, results have become progressively more and more acceptable so that now in good hands excellent aesthetics may be expected.

Of all the surgeons who actively participated in the advancements in nasal reconstruction, we particularly thank Drs John Marquis Converse, David Ralph Millard Jr, Gary C. Burget and Frederick J. Menick.

This is a broad topic. For the interested reader, we recommend the book by Burget and Menick² and the more recent publication by Menick.³

Surgical anatomy of the nose

The nose is a composite tissue structure composed of three layers: the nasal skeleton, an internal lining of mucosa and an external cover.

Nasal skeleton

The nasal skeleton is the supporting structure of the nose. It consists of the nasal bones and ascending processes of the maxilla in the upper one third, the paired upper lateral cartilages in the middle third, and the lower lateral cartilages (or alar) in the lower one third.

The upper lateral cartilages are attached tightly to the caudal edge of the nasal bones and the dorsal border of nasal septum,

the 'keystone area', allowing them to remain suspended above the nasal cavity. At the junction of septum and upper lateral cartilages, the dorsal border of the septum widens to form a 'T'. This broadening is crucial since it maintains the aperture of the internal valve during nasal inspiration.

The paired alar cartilages support the lower third of the nose by uniting to form a tripod configuration as first described by Anderson.⁴ The paired medial crura form the central leg of the tripod and are attached to the anterior nasal spine and septum in the midline. The lateral crura compose the two lateral legs of this tripod, and they are attached to the pyriform aperture. Between lateral and medial cruras, the dome defines the apex of the alar cartilage. It supports the nasal tip and is responsible for the light reflex of the tip. The region of fibrous connection of alar cartilages with upper lateral cartilages is known as the 'scroll' area. The normal ala does not contain cartilage but a compact stiff fibrofatty tissue. Its reconstruction has to include stiff tissues, however, to prevent collapse and retraction.

Nasal lining

The nasal lining consists of a thin layer of vascular mucosa. It tightly adheres to the deep surface of the nasal skeleton. Mobility of the mucosa is limited by this dense adherence. Consequently only the smallest mucosal defects (<5 mm) can be closed primarily.

The anterior septal branch of superior labial artery, medial internal nasal branch of anterior ethmoid artery, septal branch of posterior ethmoid artery, posterior septal branch of sphenopalatine artery and greater palatine artery supply nasal mucosa (Figure 32.1). Anterior septal branch of labial artery and medial internal nasal branch of anterior ethmoid artery may be used for lining flaps as described below.

Nasal cover

From deep to superficial, nasal skeleton is covered by perichondrium/periosteum, areolar tissue plane, musculoaponeurotic plane, subcutaneous layer (a few millimetres of fat), dermis and epidermis.

Figure 32.1 Vascularization of septal mucosa (+ elevation of an ipsilateral septal flap). (a) Superior labial artery; (b) anterior septal branch of superior labial artery; (c) medial internal nasal branch of anterior ethmoid artery; (d) septal branch of posterior ethmoid artery; (e) posterior septal branch of sphenopalatine artery; (f) branch of greater palatine artery.

Nasal vasculature runs in the subcutaneous layer. For each side of the nose, it derives from dorsal nasal artery (a branch of ophthalmic artery that courses over the dorsum toward the tip), lateral nasal artery (that branches off the facial artery or angular artery, and passes medially along the cephalic margin of the lateral crura, just above the alar groove) and columellar artery (a branch of superior labial artery). Lateral nasal artery and columellar artery generally meet over the domal region to form an alar arcade that runs along the cephalic margin of the lateral crura.

In the upper two thirds of the nose, the skin is somewhat mobile, with a slight excess. Proceeding inferiorly from the glabella, its thickness decreases over the cartilaginous dorsum and upper lateral cartilages. Conversely, as it reaches supratip, tip and ala, the skin becomes thick, sebaceous and tightly adheres to the alar cartilages, limiting its mobility. Thus, whatever the design, local flaps will generally mobilize the two upper thirds of skin excess to resurface inferior defects.

Principles of reconstruction

Defect analysis

Except for microvascular transfer, most nasal reconstruction procedures are technically simple. A good analysis of the defect and design are vital for good aesthetics and functional outcomes.

Defect analysis will determine the size, location and thickness of the defect, quality and laxity of the remnant skin and lining, skeleton loss, local and regional scar or graft. Good-quality photographs are recommended.

Wound retraction, where present, gives the illusion of a smaller defect. Mental recreation of the original defect is essential in the reconstructive design. A functionally patent

Figure 32.2 Aesthetic subunits of the nose: 1 dorsum, 2 sidewalls, 1 tip (can be divided in two hemi-tips), 2 alar lobules, 2 soft triangles, 1 columella.

nasal airway as well as a good aesthetic outcome are basic reconstructive aims.

Three-layered reconstruction

Overlooking a lining or cartilage loss because it is hidden by skin covering will lead to retraction, collapse and landmark distortion. A three-layered reconstruction is essential to any success.

Subunit principles

As described by Millard⁵ and modified by Burget and Menick,^{6,7} the naturally lit ridges and shadowed valleys of the nose divide its surface into several more or less concave surfaces called aesthetic subunits (dorsum, sidewalls, alar lobules, soft triangles, columella and tip that can be divided into two hemi-tips) (Figure 32.2).

When a skin defect greater than 50% of a convex subunit area is repaired with a transposition flap, it is often better to discard the remnant skin of this subunit and resurface it entirely to avoid a patchwork appearance. This will then place the scars in natural ridges and valleys at the border of the cosmetic units rather than break off the continuous surface of the subunit. Furthermore, when trapdoor contraction occurs, the entire reconstructed subunit bulges, which leads to further aesthetic distortions. For Menick,³ this rule does not apply to the repair of dorsal or sidewall defects, which have indistinct border outlines and relatively flat surfaces, where skin grafts do not undergo trapdoor contraction.

Small and superficial defects

Nasal defects can be classified in two different groups: small superficial defects and large and/or full-thickness defects. The first group will need a skin replacement whereas the second will

necessitate a three-layered reconstruction consisting of inner lining, cartilage and skin. Obviously, defect analysis and reconstruction technique will be completely different for each case.

Small and superficial defects entail the loss of skin and underlying subcutaneous fat or muscle that can be left to heal by secondary intention or repaired by direct closure, full-thickness graft and local skin flaps. Such defects can generally be repaired with a one-stage procedure.

Secondary intention healing

Provided that the wound bed is well vascularized, almost every superficial defect of the nose can heal spontaneously. For example, after rhinophyma excision, it is possible, and often a good choice, to let the entire nose surface heal by secondary intention.

Granulation tissue, epithelialization and wound contracture will lead to a flat, thin, shiny and atrophic scar, at least at the beginning. Thus, the best results will be obtained in thin skin areas and flat or concave surfaces (two upper thirds of the nose). Conversely, use of this method for defects encompassing adjacent landmarks or the alar rim would result in distortion of the shape and normal appearance of the nose.

Finally, in our opinion, secondary intention healing finds its best indications on sidewalls (especially near the internal canthus) and dorsum defects. It can also provide good results on the tip and in alar regions when the defect is small (less than 5 mm) and more than 8–10 mm away from the alar rim. The postoperative care is easy. The patient just needs to wash the wound every day and cover it with a moist dressing. In our experience, no antibiotic or local antiseptic is necessary.

Direct closure

When certain that it will not distort the nasal landmarks or result in nostril margin retraction, direct closure is always the best technique. It will generally leave a good-quality scar, especially when its axis is longitudinal and in the midline. Undermining is often necessary in order to decrease tension.

It is generally possible to directly close wounds up to 1 cm in the two upper thirds of the nose where there is a slight excess of skin. Conversely, we do not recommend it in alar, tip or columella, which are areas of poor skin laxity, as it would distort landmarks and retract the nostril.

Full-thickness graft

Despite their unpredictable final outcome, full-thickness skin grafts can be a good method in many cases, provided that the recipient bed is well vascularized. Like every skin graft, immobility and direct contact with the recipient bed is vital. With this end in view, we employ quilting sutures and tie-over dressing, using a petroleum gauze. Generally, it is removed within 4–7 days, and earlier if any signs of infection are noted.

Preauricular, retroauricular, supraclavicular and forehead skin (this last one is thicker and stiffer) are the best donor sites, with good colour and texture match. Depending on the wound's depth, it can be employed as a full-thickness skin graft or as

a composite graft if underlying soft tissue is carried with the skin. In general the greater the soft tissues included, the better the outcome and the higher the risk of graft failure.

In general, skin grafts can provide good results in thin skin and flat areas such as dorsum, sidewall and columella, whereas it is a poor match in thick and sebaceous skin zones such as ala, tip and supratip (forehead skin is probably the best donor site in these locations³).

Local skin flaps

Local skin flaps mobilize the slight excess of skin within the upper two thirds of the nose and glabellar zone. Unlike skin grafts, the colour and texture of such flaps are predictable since the intrinsic blood supply of the raised skin is preserved. As they are also thicker than grafts, they can better supply missing subcutaneous tissue, but should not be an option when a significant cartilage support is missing. In such cases, the reconstructed cartilage framework would most likely not resist the skin tension of a local flap and would risk losing its resistance and shape, leading to collapse and landmark distortion.

Many local flaps have been described and we present some of the most frequently used below.

Rieger's flap

Described by Rieger in 1967,⁸ the dorsal nasal flap is vascularized by vessels of sidewall and medial canthus. Skin, subcutaneous tissue and muscles of the two upper nasal thirds and glabellar area are elevated just above perichondrium and periosteum and mobilized toward the lower third of the nose (tip and supratip). A dog-ear is excised inferiorly and glabellar donor site is then closed with a V-Y closure (Figure 32.3). Mobilization of this flap can be emphasized by Marchac's modification⁹ that narrows the pedicle around the only medial canthus zone with a counter-incision at the junction between cheek and sidewall.

Despite this, even for defects smaller than 1.5–2 cm tip and supratip defects, we do not use this flap frequently. This is because of differences in skin thickness along the wound margin and because its inferior border often leaves a visible and depressed scar crossing the round tip subunit. Additionally, it tends to retract alar rim, approximates eyebrows and creates a radix fullness that often necessitates a revision.

Bilobed flap

Zitelli's bilobed flap¹⁰ is a double transposition flap widely used for defects up to 1.5 cm in diameter located in the lower third of the nose (Figure 32.4).

The first lobe is designed adjacent to the defect with the same diameter. The second one is adjacent to the first one, slightly smaller and has to lie in an area of laxity to allow its direct closure (two upper thirds). The angle of transposition is approximately 45° for each lobe. In general, the flap is based laterally for tip and supratip defects and medially for alar defects.

After resection of the inferior dog-ear between pivot point and defect, the flap is incised and elevated. We recommend wide

undermining of the defect borders, flap base and donor site just above the perichondrium and periosteum in order to facilitate transposition and minimize distortion. The first lobe is then mobilized to cover the defect and the second one shifts to repair the second defect created by the first lobe. This final defect is closed with direct suture.

Even if lower skin of the nose is resurfaced with a well-matched nearby skin, the surgeon should be cognizant that swelling may be significant; persistent erythematous scar and nostril retraction when it lies less than 1–1.5 cm away from the margin, often obliterating the alar crease, are major considerations. The patient should be advised that revision is often necessary.

Single-stage regional skin flaps

Regional skin flaps mobilize skin of nearby units of the face from the glabellar and nasolabial area.

Glabellar flap

Like the Rieger's flap, laxity of the glabellar area is used to cover defects of dorsum, medial canthus or lateral wall. Based on the medial canthus, it can be mobilized using advancement, rotation or transposition.

As the donor site is closed with a V-Y closure, it leads to eyebrow approximation. It also often creates differences in skin thickness along the wound margin. For these reasons we generally keep this procedure for frail elderly patients who need a simple and one-stage reconstruction.

Single-stage nasolabial flap

Directly adjacent to the nasolabial fold, excess skin of the medial cheek can provide very good-quality skin for lateral defects of the nose. The colour and texture are very similar to those of alar and sidewall.

Single-stage nasolabial flap is generally indicated for defects of alar and sidewall up to 2 cm in width (Figure 32.5). This size corresponds to the maximum width of skin that can be harvested in the medial cheek without leading to unacceptable distortions of the nasolabial fold or asymmetry of the oral commissure due to excessive tension during donor site closure. (If more than 2 cm in width is needed for a total alar subunit, for example, the pattern will have to lay parallel to the nasolabial fold, therefore a two-stage flap will be necessary.)

In contrast to the two-stage flap, the single-stage nasolabial flap mobilizes the excess skin of the medial cheek as a random

Figure 32.5 One-stage nasolabial flap. Source: Dr B. Sarfati. Reproduced with permission.

pattern extension of a cheek advancement. It means that the blood supply is not by arterial perforators of facial artery but from subcutaneous and dermal vessels of the cheek. The nasolabial fold has to be outlined on an awake patient, especially in young people, as the crease can be indistinct and only a wide smile can precisely locate it.

Prior to skin replacement, an extra-anatomical cartilage graft should brace the lining to prevent collapse and nostril margin retraction. This graft should be quilted to lining and be of good shape and size. In this location, we use conchal cartilage because of its natural round shape. The flap is designed immediately adjacent to the crease. Considering the position of the pivot point and angle of flap transposition, it can be difficult to determine exactly at which height the pattern of the defect should be positioned to inset without tension. The distal margin of the flap lies in the dog-ear and may be trimmed at closure. Thus only the maximum width of the defect needs to be measured at the nasolabial fold.

The nasolabial flap and its distal dog-ear are incised and raised in continuity with 2 or 3 mm of subcutaneous fat. The lateral incision should not extend higher than the top of the nasolabial fold. This may compromise the blood supply. The cheek is then elevated just above the superficial musculoaponeurotic system (SMAS). The wider the nasolabial flap, the more extensive the cheek undermining required in order to decrease tension at closure.

The cheek flap is advanced and attached to deep tissues with solid underlying long resorption sutures along the groove between nose and cheek. This fixation is of vital importance as it will recreate this groove (otherwise a fullness appears), close the nasolabial incision and eliminate tension on the nasolabial extension flap. A dog-ear appears on the sidewall, just above the defect, and should be trimmed.

Ideally, the alar crease may be recreated with quilting sutures between the flap and lining, at the superior border of the cartilage graft. Great attention is given to blood supply and, in case of doubt, quilting sutures should be removed. Finally the flap is thinned again, if necessary, precisely trimmed on its distal margin to fit perfectly, and all incisions are closed.

We often use the single-stage nasolabial flap for elderly or fragile patients. In such cases, this technique is efficient and generally provides acceptable aesthetic results. Nevertheless, its maximum width of 2 cm (often less on young patients) often precludes reconstruction of a total ala following the subunit principles. For this reason, each time a patient demands the best procedure in terms of results without consideration for number of stages, we prefer the two-stage nasolabial flap or forehead flap.

Large and/or deep defects

Rather than purely relying on measurements, we prefer to consider defects that we know will necessitate at least a two-stage procedure. In many cases, it is possible to close a defect (even a

full-thickness one) with a one-stage technique, but cosmetic and functional outcome would be greatly improved with a multistage approach. In such cases, the different possibilities have to be discussed with the patient in terms of result, total time and number of operations. In our experience, this is only a concern for elderly or very fragile patients.

Even in larger defects greater than than 1.5–2 cm defect remnant skin of the nose may be sufficient to close the defect but insufficient to resurface nasal skin without any distortion of landmarks and rim or columellar retraction. A large skin graft is always an option, but colour, thickness and texture are unpredictable and may well not be satisfactory, especially in the lower part of the nose. In such cases, additional skin mobilized from the cheek or forehead should be used, which necessitates at least two stages.

Concerning the depth of the nasal defect, as soon as it involves cartilage, the reconstruction needs cartilage replacement. If support is not restored, it will lead to cosmetic failure (landmark deformities, nostril and columella retractions) as well as functional problems (nasal airway collapse). A cartilage graft precludes use of a skin graft. The columella, infratip lobule and defects very close to the nostril rim will generally need additional skin in order to avoid distortion in these delicate areas.

Skin replacement

Large and/or deep defects need additional skin and it is sometimes necessary to harvest this from a distant location (Washio flap or distal free flap). The best skin match is the skin closest to the defect and therefore the best donor sites are medial cheek and forehead.

Two-stage nasolabial flap

First stage

This flap will transfer the excess skin of the medial cheek to the lateral part of the lower nose, directly adjacent to the nasolabial fold. In our clinic, we only use it for reconstruction of the entire alar subunit. When harvested in two stages, nasolabial flap is vascularized by perforators vessels coming from facial artery and crossing the muscular plane below, through and above levator labii muscle. Therefore, this flap is a transposition island flap, with the pivot point located at the junction between cheek, alar groove and lip. The nasolabial fold has to be outlined on an awake patient.

A very precise template of the contralateral alar subunit is then transposed adjacent to the nasolabial fold (Figure 32.6). As the flap will be transposed with an angle of about 110°, one should place the medial part of the template distally in the flap. Positioning of the template has to be calculated to reach the ala without any tension. It is usually positioned just above the oral commissure.

Before harvesting the flap, it is strongly recommended to brace the lining (reconstructed or not) with a cartilage graft to avoid collapse and alar rim retraction. Despite lack of cartilage

Figure 32.6 Two-stage nasolabial flap. (a, b, c) After alar subunit excision, a cartilage graft is positioned. The flap is then designed directly adjacent to the nasolabial fold (probably too high in this case), elevated in the subcutaneous plane and sutured. (d) Result six months after the pedicle division.

support in the normal ala, the fibrofatty middle layer is normally able to act against collapse during nasal inspiration. However, with a significant amount of alar skin loss, this ability decreases and collapse is more likely to occur. Furthermore, this cartilage graft will help to recreate the round shape of ala and its upper and external border will design the alar groove. In this location, we use concha cartilage because of its natural round shape. This graft will be designed a few millimetres smaller than the skin template.

The flap is elevated where possible. We prefer general anaesthetic since infiltration would distort the landmarks of the nasal subunits and nasolabial fold, and adrenaline will make blood supply difficult to evaluate during the procedure. Dissection is performed from distal to proximal. The distal part of the flap is elevated with 2 or 3 mm of fat to avoid secondary thinning of this region, but dissection becomes deeper as it reaches the perforators area. In this medial part, the subcutaneous base is protected and dissection has to be gentle, with small scissors in order to keep the perforators. There is no

reason to cut muscles. Once the flap reaches the defect without any tension, undermining is stopped and the medial part of the flap is precisely sutured to the defect. The surgeon should be aware that, although reliable, blood supply is more fragile than that in the forehead flap, and distal necrosis may occur where there is tension (even slight) or extensive dissection of the pedicle. For the same reason, we do not use the nasolabial flap as a real propeller flap. We consider this a risky proposition without improving the final result.

Before donor site closure, depending on the flap's width and cheek's laxity, the cheek is more or less undermined to decrease tension and oral distortion. Concerning the inferior dog-ear, we like to harvest it with the flap and trim it just before suturing the flap. It may be used to handle the flap without injuring its distal blood supply.

Second stage

Although we prefer to wait four weeks, many authors perform pedicle division after three weeks.

As it is already thinned during elevation, the medial part of the flap does not need additional work. Conversely, as dissection was deep in this area during the first stage, the lateral part is thick and bulky. Therefore, after division, the external skin flap is re-elevated and thinned, keeping just 2–3 mm of underlying fat. The tail is then sutured and the superior dog-ear (the flap's pivot point) is excised.

In general, the skin colour matches well with the remnant nasal skin and the trapdoor effect will contract the flap into a sphere shape, which will often improve the result with time. A good design and location of the donor site makes the final scar hardly visible. Nevertheless, in some cases the cheek may be flattened and necessitate a contralateral excision of nasolabial fold to re-establish symmetry.

This technique usually provides good cosmetic results and for reconstruction of the entire alar subunit we feel this is its only indication. As soon as a defect involves part of the tip or sidewall, we prefer to use a forehead flap, which is also an excellent option for alar reconstruction.

The two-stage paramedian forehead flap

The forehead skin¹ is by far and away the best for nasal reconstruction. Its colour, texture, thickness and amount of available tissue make it our first choice for large and/or deep defects.

Forehead flaps have been described and used in numerous fashions and designs, depending on its blood supply (one or two supratrochlear arteries, supraorbital artery, superficial temporal artery), its localization on the forehead (median, paramedian, lateral) and its axis (vertical or oblique).

For us and for most authors, it is now clear that the best option is the paramedian forehead flap vascularized by just one supratrochlear artery. In our opinion, the converse scalping flap¹¹ does not increase the amount of forehead skin transfer and is a high-morbidity procedure for the patient, will temporarily blind one of the patient's eyes with a large, heavy, hairy and uncomfortable pedicle, and necessitates the use of an evident and unsightly skin graft to resurface the lower forehead, just above the eyebrow. With regard to the oblique forehead flap that is still widely used when the forehead is supposed to be too short, we think that it leads to a much more visible scar and is a more risky proposition, unless the frontalis muscle is harvested along the entire pedicle length. In addition, this leads to unattractive paralysis of the hemi-forehead.

Conversely, the paramedian forehead flap is very reliable and can provide enough skin to resurface the entire nose. The lower part of the scar is generally almost invisible and, if designed narrow enough, the eyebrow approximation is very acceptable. Concerning the upper part of the donor site that is often too wide to allow direct closure, we advise against skin graft that could be a temptation to close the defect. In our experience, skin graft matches the forehead remnant skin very poorly. It produces a strong 'patchwork' effect due to its thickness, difference in colour and texture. Furthermore, it will stop the contraction

of the wound that would decrease the size of the final scar. The authors consider that, even for a very wide flap, secondary intention healing provides the best result. It will heal in a few weeks with a daily wash and dressing, leaving a significantly smaller scar because of contraction. This scar is red at the beginning but it will become paler with time and may be hidden by hair as it lies in the upper part of the forehead. After several months, in some cases, a new laxity of forehead can allow a scar revision to make it more narrow.

Vascularization

It is now well known that only one supratrochlear pedicle is able to supply a forehead flap resurfacing the entire nose. This artery is a branch of the ophthalmic artery, which originates from the internal carotid artery. It leaves the orbit at its medial angle, crosses the orbital rim under the lion's wrinkle, between corrugator and frontalis muscles, before coursing vertically upwards.

It is at first subperiosteal, but as it passes over the brow it lies above the periosteum, protected by the corrugator first and then by the frontalis. This means that above the orbital rim the flap can be safely elevated over the periosteum. Under the orbital rim, dissection has to be under the periosteum. At about the mid-forehead level, the artery will course through the frontalis muscle to lie in the subcutaneous plane, increasingly becoming superficial as it reaches the hairline.

First stage

When the nasal defect is lateral, the flap is harvested on the same side. When it is median, it can be elevated on either sides. (hairstyle is considered when choosing the side in order to hide the upper part of the scar).

The lion's wrinkle has to be outlined on an awake patient, especially for young people. This is sometimes invisible and only a wide grimace will allow the surgeon to precisely locate it. It is recommended for safety to verify the location of the supratrochlear artery preoperatively with Doppler.

Where possible, we prefer to perform this surgery under general anaesthesia because infiltration would distort the landmarks of the nasal subunits and adrenaline makes the blood supply difficult to evaluate during the procedure. If a significant amount of cartilage is missing, the lining has to be braced with cartilage grafts before harvesting the flap. This will avoid collapse, retraction and landmark distortions.

A very precise template of the defect (respecting the subunit principles and, when intact, derived from the contralateral side) is designed and transposed to the paramedian forehead, just off the midline. This is positioned as high as possible, but below the hairline if possible to avoid hair transfer to the nose.

The pedicle of the flap is then marked out, narrowed from the pattern to the lion's wrinkle. The base pedicle width can be 1.2–1.5 cm in width. The blood supply is thus safe and a narrow pedicle will augment the arc of rotation, decrease closure tension and limit approximation of the brow.

The flap is elevated vertically downwards. As a two-stage flap, the distal part of the flap is thinned directly at this first stage. This means that it is elevated with a few millimetres of fat (trying to obtain the same thickness as the remnant skin of the nose), but respecting the frontalis muscle. This decreases blood supply and may lead to local necrosis in smokers or in very large flaps. (In such cases, it may be safer to elevate the flap with muscle and plan an intermediate stage for thinning.)

About 1 cm above the mid-forehead level, dissection goes under the frontalis muscle (but over the periosteum) to protect the artery. It can stay in this plane until the brow, after which dissection should continue under the periosteum. The flap is then rotated medially and when the paddle reaches the defect it can be closed precisely without tension in a single layer.

We like to use thin quilting sutures for 2–3 days in order to prevent haematoma and to help to recreate natural creases of the nose, such as the alar crease. Even gently tied, they can jeopardize the distal blood supply. For this reason, the flap has to be checked 1–2 h after surgery and if there is any doubt they are removed.

The forehead is then undermined on both sides in the subgaleal plane to decrease tension and precisely sutured in layers. Special care is given to maintaining eyebrow level during closure (one should not elevate the ipsilateral one). If the upper part is too wide to be closed, it will heal by secondary intention. It does not distort the brow and the final result is generally better than a skin graft.

Finally, for the comfort of both patients and nurses, we always skin graft the pedicle. This significantly decreases bleeding, which generally completely stops after 2 days. Obviously, this graft should not compress the artery.

Second stage

Some authors perform the second stage three weeks later. For greater safety, we prefer to wait four weeks. Before division, it is recommended to check the viability with a pedicle compression. If flap perfusion is maintained the pedicle can be divided.

After transection, the superior part of the flap is re-elevated. Excess subcutaneous tissue is excised in order to recreate natural convexities and creases of the nose. Further than 1.5 cm of distal flap margin elevation risks devascularization of the flap.

When the desired shape and thickness is obtained, the superior flap margin is trimmed to fit the defect precisely and sutured. Quilting sutures are recommended for at least 2–3 days to prevent haematoma and help recreate the natural creases of the nose. Flap perfusion has to be checked 1–2 h after surgery and there is any doubt they are removed.

Finally, the inferior forehead scar is reopened and the proximal pedicle is returned to the donor site and sutured in a small inverted 'V' with quilting sutures to avoid haematoma. It can also be completely excised, leaving a barely visible scar on the eyelid, but this will bring the eyebrows closer. We advise against a large inverted 'V' high on the forehead as they often become bulky and develop a retracted scar.

The three-stage paramedian forehead flap

Thinning the flap at the first stage could compromise blood supply in smokers or when a large flap is needed. In such cases, we advise three stages for greater safety and improved results.

Millard¹² first introduced an intermediate stage which was later modified by Burget. During the second stage, the pedicle was left intact and the distal inset was left attached up to 1.5 cm from its distal margin. This is effectively a bipedicle flap, allowing the middle part of the flap to be thinned safely; however, there are difficulties due to poor visibility, and the distal part of the flap could not be addressed at that stage.

In our practice, we prefer to use the full-thickness three-stage forehead flap described by Menick.³ During the first stage, except if a skin graft or a folded forehead flap is used for lining replacement, primary cartilage grafts are placed. Then, a full-thickness forehead flap (skin, subcutaneous fat and frontalis muscle) is elevated and sutured to the recipient bed.

In the second stage four (or three) weeks later, the flap can be completely re-elevated safely in the subcutaneous plane, with a thickness of 2 mm, due to the delay phenomenon. The most proximal part of the flap can be thinned during the final stage. The underlying recipient bed, comprising fat, frontalis muscle, scar and cartilage, is then sculpted precisely to recreate landmarks and creases. If needed, additional grafts can be used. The thinned flap is then repositioned.

Finally, division is performed four (or three) weeks later.

For us, this technique is by far and away the best with regard to both reliability and results.

Lining restoration

Restoring the lining is, of course, of primary importance. Even if hidden by skin resurfacing, leaving a lining defect precludes the use of cartilage grafts and will always lead to poor results. The raw undersurface of the flap will contract during secondary healing and create distortions of the shape and obstruct the airway.

Full-thickness skin graft

A full-thickness skin graft can be used in different ways for nasal lining. It will provide a thin reconstruction but will tend to retract and will need to be strongly braced by cartilage grafts.

Prefabricated forehead flap

The prelaminate forehead flap was first described by Konig. Later, it was popularized by Gillies¹³ and then modified by Converse.¹⁴ In this technique, the flap lining and cartilage framework is first built on the forehead and then transferred onto the nose.

The first stage consists of designing a precise template of the skin defect and another one for the lining defect. The template of missing skin is transferred to the forehead, exactly like a traditional forehead flap. Only the distal part of the flap is incised and undermined between frontalis and periosteum.

A full-thickness skin graft is then harvested with the template of the missing lining. This skin graft is sutured with fine absorbable sutures to the underside of the frontalis muscle.

Finally, cartilage grafts are inserted in a tunnel between skin and frontalis muscle. In order to maintain maximum connection between the skin and muscle, when possible, it is better to introduce the cartilage grafts through an incision on the lateral border of the flap. Four weeks later the flap is completely elevated, positioned and sutured into the defect. Before division, an intermediate stage can be added.

We do not feel that this technique has great advantages for the patient. The number of stages is not reduced and it is difficult to obtain optimal results because precise positioning of the cartilage framework is difficult to achieve given that the 3D shape is difficult to predict when the flap is still flat on the forehead.

'Classical' skin graft

Although it has been used in many ways for a long time, the classical skin graft has given poor results for the restoration of nasal lining. Menick recently modified the technique.³ A full-thickness skin graft can be sutured to the borders of the lining defect. Then a full-thickness forehead flap is elevated and positioned on the nose. Quilted absorbable sutures fix the graft to the flap. A skin graft naturally precludes the use of a cartilage graft.

Four weeks later, during an intermediate stage, the flap is re-elevated with 2–3 mm of subcutaneous fat. Excess scar, subcutaneous tissue and frontalis muscle is excised from the recipient bed. The graft is normally well vascularized and the cartilage framework can be placed without compromising the graft vascularization. Finally, the flap is replaced and sutured to the nose. Four weeks later, the pedicle is divided.

In our experience skin graft take is often unpredictable and for this reason the patient is checked regularly. If the skin graft fails, it can be replaced with another, delaying the intermediate stage.

Hingeover flaps

After a full-thickness amputation, sutured together or not, remnant skin and lining will join by scar. After several weeks (6–8 depending on authors) neighbouring skin vascularized across the scar can be elevated and hinged over to replace lining. These flaps are often thick and not easy to shape with a cartilage graft as they contain scar tissue. Nevertheless, they can be very useful for small defects or in association with intranasal lining flaps when a few millimetres of lining are required.

Intranasal lining flaps

All of these lining flaps can be used alone or in an association. Although well vascularized, we advise against their use in smokers. They are generally used with primary cartilage grafts and should be used if necrosis of the lining leads to cartilage graft exposure, resulting in probable infection and graft resorption.

They can be technically difficult to perform, especially when the full-thickness defect is small due to poor visibility. Even when strongly fixed with cartilage graft, such flaps will often tend to retract toward their pivot point, which means inside the nose. For this reason, stenosis regularly occurs and can necessitate a revision. Additionally, lining flaps will often lead to bleeding and crusting that can obstruct airway and compromise patient comfort. Nevertheless, they are often very useful for lining restoration.

Residual nasal lining advancement

When the lining defect is less than 4 mm along the nostril rim, the remnant vestibular lining can be separated from alar (and upper lateral cartilage if needed) to be pulled downward. To avoid secondary retraction, this lining advancement has to be braced in position with a primary cartilage graft.

Bipedicle flap

In the same area, if the lining defect is bigger, intact vestibular skin can be freed from cartilage and incised superiorly. Thus, a bipedicle flap can be moved caudally. A new superior lining loss is created and has to be restored by another flap, generally an ipsilateral septal flap.

Ipsilateral septal flap

Described by Burget and Menick,^{2,16} this flap is vascularized by the septal branch of the superior labial artery (Figures 32.1, 32.7 and 32.8). This artery comes from the facial artery and passes medially through the orbicularis oris muscle, at the junction between skin and vermillion. Just lateral to the philtrum, it gives rise to the septal branch that goes vertically upward from lip to septum, passing laterally to the nasal spine.

This branch is theoretically able to vascularize the entire ipsilateral septal lining. Thus, an ipsilateral septal mucoperichondrial flap can be elevated from posterior to anterior and can restore lining losses of the lower third of the nose. When the defect is small this flap can be challenging to harvest because of poor visibility.

Contralateral septal flap

This flap is vascularized by the medial branch of anterior ethmoidal artery that runs parallel to the dorsum, less than 1 cm from it (Figure 32.9). After elevation of the ipsilateral mucosa (used as a flap too or replaced after contralateral flap elevation, depending on lining loss), the septal cartilage is removed, preserving a septal 'L' strut for nasal support. Then a dorsally based flap of contralateral septal mucosa is incised, maintaining at least 1 cm of its dorsal blood supply. This flap is then swung laterally in order to line the mid-vault. Finally, if the ipsilateral mucosa is not used to line the lower part, it is replaced in order to repair the fistula. (In its first description, De Quervain¹⁵ used this flap as a chondromucosal flap, keeping the cartilage attached to mucosa, but it seems easier to us to remove it before cutting the flap.)

Figure 32.7 Elevation of an ipsilateral mucosal flap based on the anterior branch of the superior labial artery. Source: Dr Warren Noel. Reproduced with permission.

Ipsilateral and contralateral flaps are frequently used for large defects of the hemi-nose (Figures 32.10, 32.11 and 32.12). This will result in a fistula which is unlikely to whistle due to its width.

Septal pivot composite flap

This flap, described by Burget and Menick,² is useful for central full-thickness defects of the lower half of the nose (Figure 32.13). It will provide the dorsal support and restore lining of the mid-vault, but it is not able to restore lining of the entire lower third of the nose.

Figure 32.8 Twist of an ipsilateral mucoasal flap sutured to the ala. Source: Dr Warren Noel. Reproduced with permission.

It can be used when amputation leaves the posterior part of the septum intact, which is normally the case. The minimum required is that the remaining septum is flush with the face. If the resection involves more of the septum, the septal branches of the superior labial arteries are probably cut and flap survival is poor.

The full-thickness septum is cut superiorly, posteriorly and inferiorly until 1.2 cm from the nasal spine. In the region of the nasal spine, the mucosa is preserved as it contains the two septal branches. The flap is now only retained by attachments between cartilage and nasal spine. Therefore mucoperichondrium has to be very cautiously separated from each side in this region in order to cut the septal cartilage attachments without compromising vascularization. The composite flap is then rotated forward, out of

the nose, and fixed superiorly to nasal bones and/or upper lateral cartilages. This will recreate the midline support of the nose.

Regional flaps

The use of a nasolabial flap for lining was popularized by Millard.¹² Vascularized by perforators from the facial artery, it can restore the lining of alar bases and vestibule. Nevertheless, because of the risk of necrosis with proximal dissection and of not being able to thin the flap adequately we prefer to find another solution, otherwise there is a risk of airway obstruction and lateral displacement of the alar base.

A second paramedian forehead flap can be used to resurface a hemi-nose lining defect. However, if the cause of amputation was a skin malignancy, one should always consider the risk of recurrence and that the patient may require another forehead flap.

Source: Dr Warren Noel. Reproduced with permission.

The superiorly based facial artery musculomucosal flap described by Pribaz *et al.*¹⁷ can also be used to reconstruct the mid-vault.

Three-stage folded forehead flap

Until recently, folding the end of a forehead flap for lining reconstruction was a traditional two-stage method. Adding an intermediate stage, Menick¹⁸ modified this technique and it has become our preferred technique for the reconstruction of unilateral and bilateral defects of up to 3.5 cm in the lining. Preserving septal lining minimizes bleeding, permanent crusting and intranasal retraction of lining flaps.

During the first stage, a precise template of the missing lining is transferred to the forehead as an extension of the forehead flap, distally to the missing skin pattern. If required, this pattern can lie in the hair line as it will replace lining. A few millimetres of extra skin are added between the two patterns in order to fold the flap more easily during its inset. After elevation of the full-thickness forehead flap, the distal lining extension is folded inward and sutured to the residual mucosal lining. No cartilage graft is added at this stage.

A marginal incision is performed 3–4 weeks later and the proximal part of the flap is completely re-elevated, leaving the reconstructed lining on the nose. Each side of the flap is defatted and sculpted before the cartilage framework is precisely reconstructed. Before closing (or during marginal incision) the surgeon should note that the extra skin area has to be precisely removed. Finally, the flap is sutured back onto the nose. The pedicle is divided 3–4 weeks later. This is one of our most favoured techniques (Figure 32.14).

Distant free flaps

When the lining loss is too great, microvascular distant tissue transfer must be considered. The radial forearm free flap is the most commonly used for inner lining reconstruction due to its thinness and its reliability. This is harvested suprafascially and is anastomosed to the facial or neck vessels.

When a free flap is needed we advise coverage with a temporary skin graft. Two months later, the skin graft is excised to allow thinning, the addition of cartilage grafts and resurfacing with a two- or three-stage forehead flap.^{19,20}

Structural support

After nasal amputation, the bone and cartilage framework has to be replaced to recreate both strong support and the normal landmarks of the nose. If not precisely replaced, whatever skin and lining reconstruction is used, the result will be poor in terms of aesthetic and functional outcome.

With unilateral reconstruction the cartilage framework aims to recreate the contralateral hills and valleys as precisely as possible. When the defect crosses the midline the surgeon must determine the dimensions of the nasal reconstruction.

The ideal time for the reconstruction of the structural support is during the primary, intermediate or final stages rather than secondarily. It is possible to perform small augmentations and refinements with grafts but the skin is more difficult to mould and a complete framework will be difficult to recreate at this time.

Septal cartilage is very efficient for columellar strut, only dorsal graft, tip grafts and sidewall grafts. A dorsal and caudal L has to be preserved for midline support and tip projection.

Conchal cartilage is very useful for alar reconstruction because of its natural contour. Sutured back to back, two pieces of ear cartilage can also create a straight columellar strut or dorsal only graft. It can be harvested through an anterior or posterior incision. As long as 5 mm of posterior wall and the root of the helix are preserved, almost the entire concha can be safely harvested.

For larger defects and strong midline support, rib cartilage is the best material. Our preference is the floating ninth and tenth ribs because they curve less than the sixth. This can be used for columellar strut, sidewall and dorsal graft. They are easily harvested from medial to lateral through a 2–5 cm incision with care to avoid a pneumothorax.

Bone is not generally used due to the risk of resorption and graft exposure.

Grafts must be precisely designed and curved to obtain the optimum shape. Horizontal mattress sutures can increase or decrease convexity and the grafts must be sutured firmly to residual skeleton, other grafts and to lining using PDS or permanent sutures.

Midline support

L-Strut technique

The L strut consists of a longitudinal piece of cartilage that is seated on the nasal radix and extended along the dorsum to the tip. The caudal part of the L is strongly sutured to the anterior nasal spine with X sutures.

Hinged septal flap

Described by Millard,²¹ this L-shaped flap is carved from the remaining septum and hinged on the caudal end of the septal bones. As it pivots upward, it augments the nasal angle and recreates the dorsal support. The caudal part of the L is strongly sutured to the anterior nasal spine.

Septal pivot flap

As described above, this can provide dorsal support as well as restoring lining of the mid-vault.

Cantilever rib graft

A longitudinal graft extending from the dorsum down to the tip, which does not require fixation support of the distal tip. Proximally it can be embedded in the frontal bone, screwed to the nasal bone, or both. In order to keep the same dorsal

(a)

(b)

Figure 32.14 Three-stage folded forehead flap. (a) Full-thickness amputation of part of the tip and part of the ala for a basal cell carcinoma. (b) Result one year after a three-stage folded forehead flap.

projection, it is often necessary to lower the nasal bone before fixing the cantilever graft.

The best material for cantilever graft is 9th and 10th ribs. Designed at the osteocartilaginous junction, the bony portion of the graft is in contact with the nasal bones while the distal cartilaginous portion keeps the nasal tip pliable and resists resorption.

Lateral support

After the restoration of the midline support, upper and lower lateral cartilages have to be reconstructed. Further extra-anatomical cartilage grafts are often required for the soft triangle, alar rim and ala. If these areas, which do not normally contain cartilage, are not braced, contraction during healing will tend to collapse and retract. Isolated alar defects are best treated with

grafts that are positioned and buried in adjacent subcutaneous pockets and secured with temporary percutaneous sutures.

Composite and extended defects

Frequently the defect may encompass several adjacent facial subunits, including the lip and the cheek. Each cosmetic area should be treated individually as each facial subunit has different reconstructive requirements that could not be recreated with a single flap. Several flaps with multiple stages will be required to recreate the features of the normal face.

The ideal nose has its foundations on a solid and symmetrical platform which should be reconstructed first and for this reason it is advised to start with maxillary, cheek and lip reconstruction followed by nasal reconstruction (Figure 32.15).

Figure 32.15 Reconstruction of composite defect. (a) After angiosarcoma resection, the defect encompasses the nose, the cheek and the upper lip (skin graft on the cheek and the upper lip). (b) Preliminary surgery consisted in replacing the wide skin graft of the cheek and lip with good-quality skin. Subunits of the lip were marked and skin graft outlined. Nasolabial flap and cheek advancement totally replaced the graft. Just six weeks later the nasal reconstruction was started. (c) Result one year after three-stage forehead flap.

²Chelsea and Westminster Hospital, London, Cromwell Hospital, London and Imperial College School of Medicine, London, UK

Anatomy

A detailed knowledge of the anatomy of the periocular region is key to carrying out safe and effective reconstructive surgery.

The marginal eyelids are composed of two structurally and functionally important lamellae. The anterior lamella consists of skin and pretarsal orbicularis oculi muscle, and the posterior lamella consists of tarsus and conjunctiva. The tarsus measures approximately 8–12 mm in height in the upper eyelid and 3.5–4 mm in height in the lower eyelid. Beyond the tarsus the eyelids can be considered to have three lamellae: the *anterior lamella* consists of skin and preseptal orbicularis oculi muscle, the *middle lamella* consists of orbital septum and eyelid retractors and the *posterior lamella* consists of conjunctiva. Fat pads lying within the middle lamella serve as useful landmarks during surgery. The lamellar components of a defect should all be considered to create functional eyelids (Figure 33.1).

The eyelids receive a rich blood supply from branches of both the internal and external carotid arteries. Knowledge of the major blood vessels within the eyelids is important to ensure adequate haemostasis during surgery. The upper and lower eyelids both receive contributions from medial and lateral. Medially, the ophthalmic artery branches to form the superior and inferior medial palpebral arteries supplying the upper and lower eyelids respectively. These arteries form the marginal arteries present in both the upper and lower eyelids. The marginal arteries run on the anterior surface of the tarsus, 4 mm from the eyelid margin in the upper eyelid and 2 mm from the margin in the lower eyelid. In the upper eyelid an additional peripheral arterial arcade runs superior to the tarsus on the anterior surface of Müller's muscle. The marginal vessels and the peripheral arcade described anastomose with lateral contributions from the superior and inferior lateral palpebral arteries, which are branches of the lacrimal artery (Figure 33.2).

Function

Eyelids serve to protect the eyes. The ability to blink is important in maintaining a healthy ocular surface and being able to close the lids forcibly to protect against trauma. In addition to these physiological functions it is important not to underestimate the role of the appearance of the eyelids in human interaction. The eyelids are an important aesthetic subunit, derangement of which can result in significant psychological morbidity.

Reconstructive options

There are many reconstructive options that should be at the disposal of the oculoplastic surgeon, ranging from 'laissez faire' to the use of local, regional and distal flaps. The options should be considered in the context of the patient not just the defect. A technique that may be ideal for a certain defect may not suit all patients. For example, the tarsoconjunctival 'Hughes' flap for a lower eyelid defect may be unsuitable if it involves the only 'seeing' side of a one-eyed patient.

Aesthetic units

The face is split into a number of aesthetic units. These units should be respected to create the most naturally appearing outcome. The whole periocular region is considered to be one unit, and is further subdivided into four subunits:

- the medial canthus above the midline;
- the lateral canthus (crow's feet area);
- the lower eyelid; and
- the upper eyelid.

In addition to these areas we would recommend considering the upper eyelid in two parts: above and below the skin crease.

Figure 33.1 Cross-sectional anatomy of the upper (a) and lower (b) eyelids illustrating the lamellar structure. Source: *Oculoplastic Surgery*, 2nd edition, Brian Leatherbarrow. Reproduced with permission of Taylor & Francis.

Skin tension lines

A number of different skin tension lines of the face have been described, varying from Langer's lines to relaxed skin tension lines. The aim of these has been to aid the surgeon in choosing the direction of their incision wisely to minimize scarring. The variety of different theories published can be confusing and contradictory. In the periocular region wound healing is generally good, with relatively little scarring and the priority in incision site/direction is maintaining eyelid function. Thus despite relaxed skin tension lines and Langer's lines running parallel with the eyelid margins, defects are often closed perpendicular to the eyelid margin to prevent lagophthalmos. If lagophthalmos

is not going to be an issue, the following recommendations are made:

- In the upper eyelid, close wounds parallel to the eyelid margin and within pre-existing creases, especially the upper eyelid skin crease.
- In the lower eyelid, close wounds parallel to the eyelid margin. Subciliary wounds and wounds lying at the cheek/eyelid junction tend to heal very well.
- At the lateral canthus, close wounds within 'crow's feet'. These can be accentuated by asking the patient to smile.
- At the medial canthus, 'webbing' of skin over the concave surface should be avoided by closing wounds on the flat of the nose without undue tension.

Figure 33.2 Arterial supply to the upper and lower eyelids. Source: Bauer & Margulis, 2004 [*Plast Reconstr Surg* 114: 98–106]. Reproduced with permission of Lippincott Williams & Wilkins.

- On the nasal bridge, wounds should be closed exactly horizontally.

In all instances careful marking of useful creases and lines before infiltration with local anaesthetic is important for accuracy.

Vector considerations

The periocular region is a complex, three-dimensional dynamic structure. There are a number of specific features that should be evaluated when considering reconstruction of this area.

- *The presence of a negative vector:* A negative vector describes the situation when the anterior surface of the cornea lies anterior to the malar prominence. This is an important feature to note when reconstructing the lower eyelid. A negative vector is a risk factor for lower eyelid retraction. This can be minimized by not overtightening the lower eyelid.
- *The circular orientation of the orbicularis oculi muscle complex:* The orbicularis oculi can be envisaged to run in a circular orientation around the eye with medial and lateral raphe. To repair a defect of the anterior lamella in this region a larger distance of the outer circumference should be closed compared to the inner circumference (i.e. a wedge shape should be closed).
- *The action of gravity and tissue restitution:* There is a tendency for tissue to return to its original position and there is a gravity effect. This is an important consideration when designing flaps to repair periocular defects. Flaps repairing defects below the canthi, where possible, should exert an upwards vector. This prevents problems with lower eyelid ectropion (e.g. a medial canthal rhomboid could be designed in a

number of ways – there are always four possible options). The recommendation is to design the flap so the tendency of the flap to return to the original site exerts an upward vector.

Patient factors

A periocular defect should be considered in the context of the patient as a whole. The patient's comorbidity, attitude to treatment, geographic location and support structure will all influence the choice of reconstructive technique.

Basic techniques

'Laissez faire'

'Laissez faire' is the principle of not interfering with the healing process of the body. It can be applied to a large range of defects, being favoured for defects in the medial canthal region and for full-thickness lower eyelid defects. The limitations of the approach should be understood. Alternative approaches should be sought if the defect:

- compromises the ocular surface (e.g. full-thickness upper eyelid defects);
- may result in eyelid malposition (e.g. lower eyelid anterior lamella defects in a lax eyelid).

Direct closure

Direct closure is an ideal technique for managing full-thickness upper and lower eyelid defects (Figure 33.3). There are no strict rules regarding the size of defect that can be closed; rather, the defect must

Figure 33.3 Direct lamellar closure of the eyelid. Source: *Oculoplastic Surgery*, 2nd edition, Brian Leatherbarrow. Reproduced with permission of Taylor & Francis.

be considered in the context of the surrounding tissue laxity. In the young patient a defect less than a third of the eyelid width may be reasonably closed, whereas in the older patient with significant laxity a defect measuring over half the eyelid width may close using this technique. The technique can be used on larger defects in the lower eyelid by carrying out a lateral cantholysis; although this risks the development of a rounded lateral canthal angle.

Surgical technique

- 1 The surgeon's preference of local anaesthetic is infiltrated throughout the region of the defect and the lateral canthus if a lateral cantholysis is being considered.
- 2 The full face is prepared with antiseptic solution and draped in a sterile fashion.
- 3 The margins of the defect are cleaned.
- 4 The defect margins are grasped with toothed forceps and approximated to each other to ensure the defect can be closed without undue tension.
- 5 If a lateral cantholysis is required it should be carried out now.
- 6 A lateral cantholysis is carried out through a conjunctival incision from the lateral canthus directed inferoposteriorly only a few millimetres.
- 7 The lateral cantholysis (if necessary) is performed in a graded fashion until adequate laxity has been generated.

- 8 Absorbable 5-0 braided suture is used to close the tarsal plate ($\times 2-3$ in the lower eyelid and $\times 3-4$ in the upper eyelid). Care is taken to ensure suture material is not visible through conjunctiva and that the lid margin and conjunctival surfaces are aligned.

- 9 Non-absorbable 6-0 monofilament suture is used to close the grey line and lash line. These sutures are placed in a vertical mattress fashion to produce a positive 'pucker' to minimize the risk of a lid margin notch. These sutures are left long so they can be secured to the skin to prevent corneal irritation.
- 10 The skin is closed with 6-0 monofilament, non-absorbable suture.

Postoperative management

A topical antibiotic ointment can be applied three times a day to both the eye and wound for up to two weeks. All sutures can be removed at 5–10 days and cool packs applied for 48 h.

The Tenzel flap

This flap is useful in the situation where there is a full-thickness marginal eyelid defect that will not close despite complete lateral cantholysis. Skin from beyond the lateral margin of the lateral commissure is recruited to form new lateral eyelid margins.¹

Figure 33.4 The Tenzel semicircular flap modified with a steeper initial incision. Source: *Oculoplastic Surgery*, 2nd edition, Brian Leatherbarrow. Reproduced with permission of Taylor & Francis.

The Tenzel flap was described to aid the closure of lower and upper eyelid defects. It is a semicircular rotation and advancement flap (Figure 33.4).

Surgical procedure

- 1 The Tenzel flap is designed by following the natural contour of the eyelid at the lateral canthus accentuating the natural curvature upwards then back down to form a semicircle. A relatively steep gradient at the lateral canthus is recommended, with some authors recommending an initial vertical cut.² The high point of the flap should remain below the level of the brow.
- 2 The flap marking is incised and extended to the plane of dissection, which should extend no deeper than the superficial temporal fascia, and should remain superficial when approaching the zygomatic arch to prevent damage to the temporal branch of the facial nerve.
- 3 A lateral canthotomy and complete cantholysis is carried out. The lateral lower eyelid should be free from all deep attachments and the margin in smooth continuation with the flap.
- 4 The flap is suspended a few millimetres superior to the intended position of the lateral canthus at the lateral orbital rim with a 5-0 braided, absorbable suture.
- 5 The original defect is closed in the manner described previously.
- 6 The lateral incision site is closed with 6-0 non-absorbable, monofilament suture.

Postoperative management

As described above.

The Rhomboid flap

The rhomboid flap is a versatile flap that is used to transpose tissue from one area to another. If designed appropriately it improves the vector of tension compared to a direct closure and recruits tissue from areas of laxity.

In periocular reconstruction the rhomboid flap is particularly useful at the medial canthus. The flap recruits lax tissue from the bridge of the nose leaving an insignificant horizontal scar across the bridge of the nose and a U-shaped scar at the medial canthus that is often well hidden by glasses.

The Hughes tarsoconjunctival flap

The Hughes flap recruits tarsus and conjunctiva from the upper eyelid to reconstruct the posterior lamella of the lower eyelid. The relatively avascular tarsus retains a blood supply from a conjunctival pedicle kept attached to the superior fornix.³ The conjunctival pedicle is divided at 2–6 weeks.^{4,5} The flap is ideally suited to reconstruct a shallow, wide full-thickness lower eyelid defect. If the whole width of the lower eyelid needs to be reconstructed the Hughes flap can be secured at its lateral and/or medial end with periosteal flaps.⁶

Surgical technique

- 1 The surgeon's preference of local anaesthetic is infiltrated throughout the region of the defect in the lower eyelid and subcutaneously in the upper eyelid.
- 2 The full face is prepared with antiseptic solution and draped in a sterile fashion.
- 3 The margins of the defect are cleaned (Figure 33.5).
- 4 A 4-0 silk traction suture is placed through the grey line of the upper eyelid and the eyelid is everted over a Desmarres retractor.
- 5 The width of the lower eyelid defect is measured.
- 6 The donor tarsus from the upper eyelid is marked – width is equal to the lower eyelid defect; height is equal to the height of the upper eyelid tarsus minus 3.5 mm. A minimum of a 3.5 mm marginal strip of tarsus should be left in the upper

Figure 33.5 (a) The lower eyelid defect is cleaned. (b) The upper eyelid is everted over a Desmarres retractor and incised leaving at least 3.5 mm between the incision and the eyelid margin. (c) Vertical incisions are made through the tarsus towards the upper border of the tarsus and the tarsus dissected off underlying orbicularis. The dissection is continued between Müller's muscle and conjunctiva to create a tarsal flap suspended from the upper eyelid by conjunctiva. Right: eyelid anatomy. (d) The tarsal flap is secured medially and laterally to remnant lower eyelid tarsus or periosteal flaps if no tarsus remains. (e) The lower border of the tarsus is secured to conjunctiva and inferior retractors. Source: *Atlas of Oculoplastic and Orbital Surgery*, Jonathan Dutton, 2013. Reproduced with permission of Lippincott, Williams and Wilkins.

eyelid to ensure it remains stable so an upper eyelid entropion does not develop.

- 7 The donor tarsus is incised and dissected from the underlying orbicularis.
- 8 The dissection is continued to a subconjunctival plane.
- 9 Care should be taken dissecting the conjunctiva from Müller's muscle to prevent excessive bleeding and conjunctival buttonholes.
- 10 The donor tarsus should now be freely mobile on a wide-based conjunctival pedicle.
- 11 The donor tarsus is secured into the defect with 5-0 braided absorbable suture ($\times 2$ at each end). If no remanant tarsus exists, the Hughes flap can be secured to periosteal flaps reflected from the lateral orbital rim or the lateral wall of the nose.
- 12 The inferior border of the donor tarsus is secured to the subconjunctival tissue with a continuous 7-0 braided absorbable suture.
- 13 The posterior lamella has now been reconstructed.
- 14 A number of techniques can be employed to reconstruct the anterior lamella.

Postoperative management

A topical antibiotic ointment can be applied three times a day to both the eye and wound for up to two weeks. The conjunctival pedicle is divided under local anaesthetic in 2–6 weeks.

Tripier and hemi-Tripier flaps

The Tripier flap is a bipediced myocutaneous flap taken from the upper eyelid to reconstruct the anterior lamella of the lower eyelid (Figure 33.6).⁷ The flap is designed to maintain myocutaneous innervation. The excellent blood supply of the eyelids means that the flap can survive with only a single pedicle (the hemi-Tripier flap), usually lateral. The flap is useful in patients with significant upper eyelid dermatochalasis with a lower eyelid defect extending to either or both the medial and lateral canthi. The flap is for anterior lamella reconstruction only, hence, if the defect is full thickness an additional technique will need to be applied to address the posterior lamella. There have been descriptions of 'reverse' Tripier flaps,⁸ using lower eyelid anterior lamella to reconstruct an upper eyelid defect, however, we would caution readers to select patients carefully if this approach is being considered due to the high risk of lower eyelid retraction. The hemi-Tripier flap can be used to reconstruct the full width of the lower eyelid, however, tenuous vascularity of the distal segment of the flap may be inadequate support for a posterior lamella graft, therefore, we use this technique for full-width reconstructions only when the posterior lamella is not being grafted.

Surgical technique

- 1 The upper eyelid skin crease is marked and a maximum blepharoplasty mark made. At least 20 mm of upper eyelid skin must be preserved. The marking outlines the largest flap that can be harvested.

- 2 The medial and lateral ends of the blepharoplasty marking are swept superiorly to define the pedicles of the flap. Efforts should be made to blend these marks into pre-existing rhytids. The flap is designed in such a way that there is traction in a superolateral and superomedial direction at the lateral and medial ends of the flap respectively.
- 3 The surgeon's preference of local anaesthetic is infiltrated throughout the region of the defect in the lower eyelid and subcutaneously in the upper eyelid.
- 4 The full face is prepared with antiseptic solution and draped in a sterile fashion.
- 5 The margins of the defect are cleaned.
- 6 A 4-0 silk traction suture is placed through the grey line of the upper eyelid.
- 7 A template of the lower eyelid defect is made.
- 8 The template is transferred to the upper eyelid, the lower margin aligned with the upper eyelid skin crease marking.
- 9 A new superior blepharoplasty incision is marked including the template plus an additional 20% height to allow for contraction.
- 10 The lower eyelid defect may need to be enlarged at the canthi to accommodate the ends of the flap.

Figure 33.6 A laterally based hemi-Tripier flap to reconstruct the lateral lower eyelid anterior lamella. Source: *Reconstructive Facial Plastic Surgery: A Problem-solving Manual*, Hilko Weerda, 1999. Reproduced with permission of Thieme.

- 11 The upper eyelid flap is dissected in the suborbicularis plane leaving the septum intact. If the flap only has one pedicle, we recommend tapering the thickness of the flap from its base to its tip to reflect the increasingly tenuous blood supply along the flap.
- 12 The flap is secured into the defect with no tension using 6-0 non-absorbable monofilament suture and the upper eyelid defect closed with the same suture material.

Postoperative management

A topical antibiotic ointment can be applied three times a day to both the eye and wound for up to two weeks. All sutures can be removed at 5–10 days and cool packs applied for 48 h.

Cheek rotation flap

The cheek rotation flap is used for total reconstruction of the anterior lamella of the lower eyelid (Figure 33.7). The posterior lamella should be reconstructed separately, commonly using a graft (see below).

Surgical procedure

- 1 The cheek rotation flap is marked by following the natural contour of the lower lid upwards at the lateral canthus onto the temple then turning inferiorly in front of the ear. As with the Tenzel flap, height of the flap is important to prevent a downwardly displaced lateral canthus.
- 2 The flap marking is incised and extended to the plane of dissection, which should extend no deeper than the superficial temporal fascia, and should remain superficial when approaching the zygomatic arch to prevent damage to the zygomatic branch of the facial nerve. The cheek dissection should be extensive to allow mobility of the flap and carried out in the subcutaneous/fat plane.

Figure 33.7 Marking for a cheek rotation flap. The 'standing cone' that would result from the flap rotation has been marked inferior to the defect – this is to be excised. Source: *Oculoplastic Surgery*, 2nd edition, Brian Leatherbarrow. Reproduced with permission of Taylor & Francis.

- 3 The flap is rotated into position.
- 4 Standing cone/dog-ear deformities may need to be excised both in the preauricular region and the cheek.
- 5 The highest point of the flap is suspended a few millimetres superior to the intended position of the lateral canthus at the lateral orbital rim with a 5-0 braided, absorbable suture.
- 6 The flap is secured with deep 5-0 braided, absorbable suture and 6-0 non-absorbable monofilament used to close the skin.

Postoperative Management

We recommend application of a firm dressing for 3–5 days to reduce the risk of haematoma formation. A topical antibiotic ointment can be applied three times a day to both the eye and wound for up to two weeks. All sutures can be removed at 10 days.

Full-thickness skin grafting

Full-thickness skin grafting is a versatile technique for anterior lamella reconstruction. There are some general principles that should be adhered to. Full-thickness skin grafts gain a tenuous blood supply from the tissue they are placed upon, therefore, to maximize the chance of viability they should be:

- *thin* – the graft should be thinned to the level of the dermal Rete pegs;
- *placed on a well-vascularized bed* – for example, when placing a skin graft on a Hughes flap, which is relatively avascular, a 'bucket handle' of orbicularis oculi muscle can be interposed to provide a more robust vascular base; in areas where there is no vascular base in the immediate vicinity, a pericranial flap can often be fashioned to provide one;
- *static* – to develop a blood supply the graft should initially be kept static on its vascular bed; this may necessitate a light compression dressing and/or immobilization of the eyelid with 'Frost' sutures.

Donor site choice

There are number of areas that skin can be harvested from; with pros and cons for each choice. All donor sites should be hair free.

- *The upper eyelid*: In patients with significant dermatochalasis, the upper eyelid can be a useful donor site. The skin here is usually a good colour match for the rest of the periocular region and is thin. Disadvantages include a relatively limited supply and the presence of sun damage.
- *The pre- and postauricular region*: Advantages include relatively insignificant donor scars and a reasonable colour match. Disadvantages include limited availability and thicker dermis.
- *The supraclavicular region*: Advantages include a donor scar that can usually be well hidden (however, counsel patients carefully as they may want to expose this region) and a relatively large reservoir. Disadvantages include occasional hairs in this area and thicker dermis.
- *The inner upper arm*: Advantages include a large reservoir and it is usually free from significant sun damage. Disadvantages include a colour mismatch and thicker dermis.

Surgical technique

- 1 The surgeon's preference of local anaesthetic is infiltrated throughout the region of the defect and the donor site.
- 2 The full face and donor site is prepared with antiseptic solution and draped in a sterile fashion.
- 3 The margins of the defect are cleaned.
- 4 A template is made of the defect using plastic drape or sterile paper.
- 5 The template is transferred to the donor site and traced around.
- 6 The skin graft is cut from the donor site – oversizing it slightly – with a combination of a blade and scissors. Cautery to the graft is not recommended.
- 7 Care is taken to thin the skin graft to the level of the Rete pegs.
- 8 The graft is sutured in place with interrupted 6-0 non-absorbable, monofilament suture.
- 9 The graft is immobilized with a light compression dressing and/or a Frost suture.

Postoperative management

The dressing can be removed 1–5 days post op depending on the size of the graft. Sutures should be removed on day 5–7. A topical antibiotic ointment can be applied three times a day to both the eye and wound for up to two weeks.

Key to the success of a skin graft is careful postoperative management. Massaging with or without a silicone dressing and steroid injection into thickened areas can be important in achieving a satisfactory outcome.

Posterior lamella grafting

The tarsus is an important structural element of the eyelids. It is responsible for maintaining a stable eyelid margin position. If there is significant loss of tarsus leading to a potentially unstable eyelid margin, thought should be given to replacement of this structure. The Hughes flap has already been discussed, however, this is not suitable for every case. Free grafts can be considered. In situations where there is no canthal tendon support either laterally or medially to secure the posterior lamella replacement, a periosteal flap can be reflected from the lateral orbital rim or side of the nose respectively.

Tarsal replacement graft donor sites

- *Contralateral upper eyelid:* The upper part of the tarsus of the upper eyelid can be harvested for use as a graft. At least 3.5 mm height of tarsal plate should be left behind to avoid destabilizing the donor eyelid. The advantage of this graft is that it is identical tissue and has a conjunctival covering. Disadvantages include possible donor site morbidity and a limited size graft.
- *Hard palate:* This has the advantage of being readily harvested in an adequate size with a mucosal covering. Disadvantages

include the potential to cause corneal abrasion as the mucosal surface tends to be rougher than conjunctiva, hence, caution should be exercised when using this in the mobile upper eyelid.

- *Auricular cartilage:* This can be used as a structural replacement for tarsus. Disadvantages include a lack of mucosal covering, therefore, this must be considered separately. The cartilage is also not flat, therefore, must be scored and sculpted to create an appropriate shape. Despite shaping, the graft often returns to its original shape that can distort the eyelid.
- *Nasal septal cartilage:* Similar to auricular cartilage, nasal septal cartilage can be used as a structural replacement for tarsus, however, it has no mucosal covering. An advantage is its relatively flat shape, disadvantages include possible donor site comorbidity (e.g. nasal strut collapse and septal perforation).

Discussion

Successful periocular reconstruction demands an intimate knowledge of the functional anatomy of the eyelids and an appreciation of aesthetics. The solution for managing a patient's periocular defect must be bespoke and often requires imagination.

This chapter does not provide a definitive guide to periocular reconstruction, but it does provide the basic tools required to manage the vast majority of situations.

CHAPTER 34

Ear reconstruction

Françoise Firmin¹ and Neil W. Bulstrode²

¹Clinique Georges Bizet, Paris, France

²Department of Plastic Surgery, Great Ormond Street Hospital for Children, London, UK

A variety of traumatic ear defects are observed after amputation, whether partial, subtotal or total, all of which require complex contour reconstruction.

There are multiple causes of ear amputations and this summary aims to define some principles and guidelines that permit a precise surgical management plan.

Initial assessment concerning a posttraumatic amputation

Mechanism of ear amputation

Clean amputations

Clean amputations are usually secondary to trauma involving a knife, surgical resection or sharp bites (animals or human). Primary treatment consists of debridement and suturing of the edges of the wound.

If we exclude surgical amputation for cutaneous malignancy, it is tempting to replant the amputated segment of ear. Many different techniques have been proposed to ensure success of such replantation (burying, fibrocartilage fenestration, cartilage storage and secondary replantation).

Whatever the degree of success of such surgical approach, the final result will be disappointing. Even though it may be difficult to make the decision not to attempt replantation and to sacrifice the amputated ear segment, this will preserve the skin potential for a superior secondary reconstruction.

Replantation should only be considered when vascular anastomosis is possible and reliable.

Crush injury

A crush injury occurs after a fall, road traffic accident, blunt trauma or violent compression. In such circumstances the ear defect is generally only part of a complex injury involving the surrounding soft tissue.

Burn injury

Thermal, chemical or electrical burn injuries are a frequent cause of traumatic ear defects. Both ears are frequently affected and the burn area extends around the auricular area. Besides the zone directly injured by the burn, a secondary chondritis often results in severe resorption of the fibrocartilage.¹ When limited to the ear, the defect usually affects the scapha and helix, but often the retro-auricular skin and scalp are also affected with scars and alopecia.

Burn patients are generally managed in a burns unit where initial stabilization and grafting are performed. Reconstruction of the ear is a last step of management. Those patients who have undergone multiple surgical procedures may opt not to have an ear reconstruction. In some cases, an ear prosthesis is indicated.

Analysis of the defect

A precise analysis of the defect is critical in all reconstructive efforts. The missing contours must be appreciated and reconstructed in all dimensions.

To correctly appreciate the defect it is essential to draw the normal ear on a transparent template, and place it on the injured ear to appreciate the missing contours needing reconstruction. Skin alone is not adequate to reconstruct the contours of the ear, and depending upon the size of the defect, either fibrocartilage or rib cartilage is required as part of the reconstruction.

Analysis of the skin potential

The specific problem encountered in cases of posttraumatic amputation is the presence of scars. It is essential to analyse their location and the skin availability to cover the reconstructed cartilage construct. The following three factors need consideration:

- The quality and quantity of skin in the auricular area must be appreciated. The presence of lax and scar-less retro-auricular skin provides the best conditions for coverage of the cartilage framework.

- Scars. After inspection of scars a surgical approach is chosen to minimize the use of new scars and ensure vascularity of the skin to cover the cartilage construct.
- Deficit of skin. In cases where there is no skin available in the auricular area, surrounding fascia (temporoparietal or occipital) or the use of skin expansion will have to be considered to cover the cartilage framework.

Reconstruction in partial amputations

Partial traumatic defects of the ear are always located along the free border of the ear. In this discussion we will exclude defects of the helix that can be closed directly or using skin flaps or chondro-cutaneous flaps. The Antia Buch flap² can be used for small defects but its principle of moving the helix after a scaphoid resection always reduces the size of the ear.

In partial amputation, skin availability is usually adequate and the main concern is to choose the best support to reproduce the missing cartilage contours. Either fibrocartilage or rib cartilage may be used. It is essential to draw the normal ear on a template, and then transpose the template on the affected ear to work out what is missing and what contours need reconstructing.

The rule is that fibrocartilage can only be used to reconstruct a partial defect after trauma if the it is no more than a quarter of the border of the ear and includes no more than two adjacent planes. Harvesting all of the concha can only reproduce two adjacent planes and just a quarter of the ear. If the defect is less than a quarter but includes three planes, then rib cartilage should be harvested to correctly reproduce the missing contours (Figure 34.1).

Figure 34.1 Fibrocartilagenous conchal graft can only be used when the defect is no more than a quarter of the ear and no more than two adjacent planes.

Reconstruction using fibrocartilage

Harvesting the fibrocartilage graft

The concha is the best donor site considering its size and the fact that it will not be visible if harvested correctly. The entire concha has to be harvested, taking care to preserve the root of the helix and enough posterior wall of the concha.

Depending on the case it can be harvested through an anterior or posterior approach from the ipsi- or contralateral ear.

The choice concerning the skin approach (anterior or posterior) depends on the defect and the skin vascularity. The choice concerning the harvesting on the ipsi- or contralateral side may be discussed with the patient, who sometimes is reluctant to have surgery performed on the normal ear.

Depending on the location of the defect and the skin potential the reconstruction will be performed in one or two stages.

The case in Figure 34.2 shows a reconstruction in one stage using an ipsilateral conchal graft. The defect is secondary to

Figure 34.2 (a) The defect is a quarter of the ear and no more than two planes. (b) The conchal graft harvested on the same ear by an anterior approach will be reduced to reproduce the missing contours. (c) Bolster sutures apply the skin to the underlying contours. (d) Result.

chondritis after trauma. It is a quarter of the contour of the ear and no more than two adjacent planes.

In the case shown in Figure 34.3, because the defect is a quarter and no more than two planes the reconstruction was performed using a contralateral conchal graft covered with retro-auricular skin. Creation of the retro-auricular sulcus behind the reconstructed part of the ear will be performed in a second stage. Elevation of the ear is performed, respecting the soft tissues behind the ear, to cover the area with a small full-thickness skin graft harvested from the opposite retro-auricular sulcus.

Reconstruction using costal cartilage

There is an abundant amount of cartilage when harvesting from the thorax but when harvesting for reconstruction of partial defects, only one segment of cartilage is required. In such situations the scar on the thorax will be short.

Harvesting cartilage is a routine procedure with minimal risk. Pain is avoided by injecting bupivacaine (Naropin USA) into the muscles.

Using only a skin flap to reconstruct a partial amputation located on the periphery of the ear cannot reproduce complex contours and will give a poor result.

It is important to differentiate cases where the entire antihelix has been preserved from the ones where part of it is missing, particularly the posterior wall of the concha. If part of the antihelix is missing it has to be reconstructed respecting the anatomical unit of the antihelix and the base that supports it.

Cases with normal antihelix

Figure 34.4 shows a clean amputation with a defect that is no more than two adjacent planes but more than a quarter of the ear of the border of the ear, requiring the use of rib cartilage support. The

Figure 34.3 (a) The defect is a quarter and no more than two adjacent planes. (b) The conchal graft harvested on the contralateral ear is sutured to the fibrocartilage and the retro-auricular skin will cover it. (c) Appearance after the first stage. (d) Result after elevation of the reconstructed contours using a full-thickness skin graft harvested from the contralateral retro-auricular sulcus.

Figure 34.4 (a) Even though the defect is no more than two adjacent planes, it is more than a quarter of the border of the ear. (b) Perfect adaptation of the sculpted rib cartilagenous graft to the contours of the other ear drawn on a template. (c) Coverage of the reproduced contours by an advanced retro-auricular skin flap. (d) Result obtained in one stage.

Figure 34.5 (a) Defect after unsuccessful replantation. (b) Rib cartilaginous graft reproducing the missing contours. (c) Skin flap covering the reconstructed contours. (d) Final result after elevation using a split-thickness skin graft harvested from the scalp.

reconstruction can be performed in one stage as there is enough retro-auricular skin to cover the narrow cartilaginous graft.

The amputation in Figure 34.5 is secondary to a human bite. An unsuccessful replantation has left a defect involving half of the inferior border of the ear, including the lobule. The reconstruction was performed in two stages with a very good result. The former scar was used to prepare the flap to cover the cartilage framework during the first stage. Advancement of the retro-auricular skin and grafting the posterior surface of the reconstructed ear was done four months later during the second stage.

In the case shown in Figure 34.6, using a rib cartilage graft on a 60-year-old patient was possible as there is no correlation between age and ossification. The texture and colour of the cartilage will just be different. The rib segments are thicker so the scapha and helix can be sculpted in one segment. Elevation of the reconstructed upper third of the ear can be performed four months later.

Cases with an injured antihelix

In cases where the antihelix has been destroyed, a framework including a base must be fabricated to be able to fix the antihelix to obtain correct projection of the antihelix and middle part of the ear.

Figure 34.6 (a) The defect is more than a quarter and only two planes (helix and scapha). (b) Cartilaginous rib graft sculpted after appreciation of the missing contours using a transparent template. (c) Good match of the graft with the contours of the ear. (d) Result after elevation of the upper part of the ear using a skin graft.

Figure 34.7 shows amputation secondary to a dog bite. It is clear that part of the antihelix is missing and that the entire antihelix anatomical unit has to be reconstructed.

Even though this patient is 52, her cartilage is not ossified and presents with the usual yellow discolouration and is particularly dense.

Total and subtotal amputation

Total amputation does not always imply that there are no auricular remnants. Total or subtotal amputation implies that most of the contours are missing and that the reconstruction has to be done with a cartilage framework reproducing all of the ear's contours with rib cartilage.

A framework will be carved from several segments of ribs. Even though many synthetic materials have been proposed as an alternative to rib cartilage, autologous rib cartilage remains the best material.

Figure 34.7 (a) The roots of the antihelix have been preserved but not the posterior wall of the concha and the inferior part of the antihelix. This case must be considered like a subtotal amputation. (b) Antihelix with its two roots is carved in one segment of cartilage and just the missing part of the helix is added on the base. This shows the typical colour of the non-ossified cartilage of a 52-year-old patient. (c) Reconstruction of the retro-auricular sulcus six months later by retro-auricular skin advancement and skin graft of the posterior surface of the ear elevated with soft tissues. (d) Result after one year.

In these cases two stages are required for ear reconstruction. The first stage involves creation of the cartilage construct with all the contours, followed by the second stage – elevation and creation of a postauricular sulcus – performed 4–6 months later.

Reconstruction technique

First stage: Reconstruction of the ear contours

The contours of the normal ear are drawn on a transparent template. Under general anaesthesia the operative field is prepared and the head is placed in a lateral position. The template is then transposed on the affected ear to correctly analyse the missing contours and to appreciate the symmetry at the end of the

Figure 34.8 (a) Only the upper part of the helix and the tragus have been preserved. (b) After drawing a template of the other ear, the missing contours to be reproduced are drawn on another transparent template.

operation. Landmarks are taken on the normal side and then transposed on the affected side to reconstruct the ear in an ideal position and axis (Figure 34.8).

The first stage includes three steps: harvesting of the rib cartilage, carving the cartilagenous framework and preparation of the skin in the auricular area to insert the framework.³

Harvesting rib cartilage

Three or four segments of rib cartilage are harvested on the same side as the injured ear. The skin approach on the thorax is oblique and located close to the inferior border of the thoracic wall. This gives access to the anterior surface of the 6th, 7th, 8th and 9th rib segments.

A template of the other ear, having been sterilized, is used to select the adequate segments of cartilage. Once selected, these segments will be harvested, preserving the posterior perichondrium. When the framework includes the helix, the 7th or the 8th segment is chosen to obtain a piece of cartilage no shorter than 7 cm in length. The template is also used to select the two adjacent segments united by their synchondrosis that are the most appropriate for the base. Preservation of the posterior perichondrium reduces the risk of injury to the pleura. Before closing the different planes, bupivacaine (Naropin USA) is injected into the muscles to minimize postoperative pain. The muscle's edges are approximated by interrupted sutures, including the anterior and posterior edges of the aponeurosis. Care must be taken to reduce the prominent residual cartilage to avoid visible thoracic irregularities. There are no functional sequelae after harvesting these segments of cartilage.

Carving the framework

With experience, this is the most routine step of the reconstruction. A specific set of instruments (Storz, Germany) and double-ended wire sutures are used to construct the framework. Using a silicone board for stabilization is very helpful.

The posterior surface of the segments, free of perichondrium, becomes the anterior surface of the base and the segments of cartilage are cleaned, removing any perichondrial remnants. The template of the other ear is drawn on a blotting paper which is dipped into ink and applied on the cartilage. The base is placed on two adjacent ribs.

The eighth rib is prepared to reproduce the helix; it can be lengthened with an additional piece if needed. It is then carved with a gouge to increase pliability. The lobule is lowered and shaped, as well as the area of the intertragal notch and antitragus. The posterior edge of the base is cut obliquely to look thinner from behind. The base is carved and a segment reproducing the antihelix with its two crus is added to give more projection to the antihelix. The antihelix is fixed on the base using double-ended wire sutures. Once added to the base, the antihelix is reshaped. The helix is then added. Its root is fixed onto an extra piece of cartilage to give more projection and stability. The overall size and shape of the framework is checked with the template.

All the double-wire sutures used to fix the construct are tightened, cut short and buried in the cartilage. In cases of trauma there is usually no need to reconstruct the tragus.

The final touch accentuates the curve of the junction between the antihelix and the antitragus. An additional piece is sometimes added behind the base to deepen the concha and increase projection.

Framework classification

We have established a classification for the different types of cartilagenous frameworks.³

- Type I is a complete framework including the tragus and the antitragus.
- Type II includes the antitragus but not the tragus.
- Type III does not include the tragus and the antitragus.

In cases of traumatic amputation the tragus is often preserved and the most frequent frameworks used are types II and III (Figure 34.9).

Insertion of the framework under the auricular skin

A correct analysis of the skin potential in the auricular area is essential to choose the best skin coverage for the framework. When the retro-auricular skin has been preserved, it represents an ideal coverage and the retro-auricular sulcus will be reconstructed during a second stage. When it has been damaged it is necessary to use temporoparietal fascia and a skin graft. If the skin is too tense to cover the tridimensional framework it is possible to use indirect expansion.

The following scenarios represent different skin conditions.

Good skin availability in the auricular area

If the retro-auricular skin has not been damaged and has not been sutured under tension it can be used to cover the framework. The skin approach to prepare the skin pocket and to insert the framework must be through a previous scar. Dissection can be performed respecting the subdermal plexus.

Figure 34.9 The most frequent types of cartilage in cases of total amputation: (a, b) all the contours except tragus must be reconstructed: type II cartilage; (c, d) all the contours except tragus and antitragus must be reconstructed: type III cartilage.

The case shown in Figure 34.10 was total amputation preserving the tragus on an adult patient 55 years old. A preoperative CT scan with 3D coloured printing is very useful to appreciate the degree of ossification of the cartilage at that age. Because the non-ossified segments of cartilage are larger and thicker, it is sometimes possible to carve the base of the framework and the antihelix in one piece and just add the helix, generally carved from the eighth costal cartilage segment. There is just enough skin to cover the 3D framework. Six months later, elevation of the reconstructed ear was performed taking into account the projection of the other ear. Here a temporoparietal fascia flap was used to cover the posterior surface of the framework after adding a crescent-shaped piece of cartilage behind the antihelix, stored since the first stage under the thoracic skin.

Good, scar-less skin but under tension

It is very important to appreciate the elasticity of the retro-auricular skin to decide if it can adapt to a 3D framework without too much tension, particularly on the helix. If not, an expander may

Figure 34.10 (a) Only the tragus has been preserved. (b) Framework type II, reproducing all the contours except the tragus. Only two segments of ribs (seventh and sixth) have been harvested. The antihelix has been carved in the base. (c) After the first stage all the contours are present but there is no retro-auricular sulcus. (d) Elevation of the ear is performed using a temporal fascia which covers the posterior surface of the ear and an additional cartilage graft placed behind the antihelix to give projection to the ear and deepen the concha. Some hair-bearing skin on the helix can also be excised.

be placed under the adjacent scalp prior to the formal first stage. This expansion is indirect expansion because it will not expand the non-hair-bearing skin in the auricular area but will increase the skin potential, which can be redistributed during placement of the framework, reducing the skin tension and avoiding the risk of skin necrosis and cartilage exposure.

Crescent-shaped expanders are used (150 cm^3) and filled over a period of 6–8 weeks.⁴

In the case shown in Figure 34.11 a type III framework was carved, as tragus and antitragus have been preserved. To avoid excessive tension and allow good adaptation of the skin to the contours, indirect expansion was used. Reconstruction of the retro-auricular sulcus can be performed six months later.

Figure 34.11 Indirect skin expansion. (a) Primary closure has been performed under some tension. (b) A crescent-shaped expander (150 cm^3) has been placed under the skin behind the non-hair-bearing skin of the auricular area, and filled. (c) The 3D framework has been inserted without excessive tension. (d) Result after elevation of the ear.

No available skin

When there are scars in the retro-auricular area that impair skin vascularity, making it impossible to cover the framework without a high risk of skin necrosis, other options are needed. A temporoparietal fascia flap based on the superficial temporal artery, if not damaged, is planned to cover the framework. This is then covered with a scalp split-skin graft. When the superficial temporal artery has been damaged it is still possible to use a random pattern fascial flap.

After shaving of the temporal area, the course of the superficial temporal artery is mapped with Doppler. A zig-zag incision is then performed on the scalp to expose the fascia. To facilitate the rotation of the fascial flap a narrow pedicle including the artery is designed and raised. Once inset, the fascial flap is covered with a scalp split-thickness skin graft, which is a superior donor site for colour match and donor site visibility.

Two or three suction Blake drains are placed during the first stage. The aims of the drains are to minimize haematoma formation and to apply the skin onto the underlying cartilage contours. The drains are removed after 3 days during the first dressing change.

Definition of the contours and the quality of the result can only be judged after a year to allow the scarring to have minimized. When elevation of the ear is indicated to create the retro-auricular sulcus, it is usually performed after one year.

Figure 34.12 shows grafting of the auricular region following a road traffic accident. A temporoparietal fascia was indicated. The temporoparietal fascia was covered with a scalp split-thickness skin graft placed on the upper two thirds of the framework. Elevation of the upper part of the ear was performed one year later.

Figure 34.12 (a) The skin of the auricular area cannot be used. The route of the superficial temporal artery has been drawn using a Doppler. A zig-zag incision allows good exposure of the fascia and reduces the risk of a noticeable scar. (b) The well-vascularized fascia flap covers the framework. (c) A split-thickness skin graft taken from the scalp with a dermatome covers the fascia. Suction drainage will avoid haematoma. (d) Result after one year and before elevation.

Second stage: Reconstruction of the retro-auricular sulcus

There are different techniques to elevate the reconstructed ear.

- Elevation of the ear, preserving soft tissues on the posterior surface of the framework. A split-thickness skin graft is used to cover the posterior surface of the ear. The posterior edge of the incision around the ear is brought forward after undermining the skin. This is the technique advocated by Brent, except that he was not using a split-thickness skin graft harvested from the calvarium⁵ (see Figure 34.6c).
- Use of a temporoparietal fascia covering a piece of cartilage placed behind the antihelix to deepen the concha and give more projection to the ear. This procedure was advocated by Nagata in cases of microtia⁶ (see Figure 34.10d).
- Improving the projection of the ear after its elevation by inserting a piece of cartilage behind the framework, into a

Figure 34.13 Prosthesis. (a) Temporal fascia cannot be used and there is no skin available in the auricular area. (b) Revision of the temporal scar and correct location of the implants. (c) Brenemark implants. (d) Prosthesis.

tunnel, which will be placed behind the anterior root of the antihelix or the antihelix or the antitragus.³

The criteria used to select the most appropriate procedure is the need to obtain symmetry concerning the projection of the ears, taking into account the local conditions. Analysis of the projection of the contralateral ear is essential before performing the second stage.

Prosthesis

In cases of poor local condition, including a severed superficial temporal and occipital arteries, the prosthetic solution should be considered. It may be indicated for older patients when rib cartilage may be ossified or when a patient has undergone multiple surgical procedures and opts for this solution.

Figure 34.14 Exposure treated by spontaneous healing. (a) Exposure of the root of the helix after elevation of the reconstructed ear. (b) Granulation of the skin edges will cover the exposed cartilage, followed by epithelialization.

Figure 34.15 (a) Large skin necrosis at the level of the previous sutures. (b) Clean exposure of the cartilage framework and drawing of the skin approach to dissect a random fascial flap (dotted line). (c) Fascial flap covered with a split-thickness skin graft taken from the scalp. (d) Final result with good colour match of the skin graft.

Figure 34.16 (a) Total amputation after human bite. The former scar in the concha is used as a skin approach to prepare the skin pocket. (b) Skin necrosis and exposure of the cartilage. (c) The temporal fascia flap has been placed in front of the exposed cartilage, avoiding any tension of the skin, and is covered with a split-thickness skin graft from the scalp. (d) Final result.

Placement of Brenemark implants is performed in one or two stages depending on local condition and auricular remnants. The result, of course, relies on the quality of the prosthesis and the good adaptation of the patient to the management of the prosthesis and the percutaneous abutments.

A patient with total amputation of the ear after an automobile accident who needed primary coverage of the temporal bone by a scalp flap is shown in Figure 34.13. The temporal artery and fascia have been damaged and there is no skin available in the scarred auricular area. Three Brenemark implants are placed in one stage, and a prosthesis by an experienced anaplastologist (Dr. Pillet) give the patient great satisfaction.

Complications

The use of suction drains correctly located and removed after 3 days helps to avoid haematomas. Unsatisfactory results may result from inappropriate planning in carving the framework or selecting the wrong skin approach. Extrusion of wire sutures, retraction of the sulcus and hypertrophic scarring may occur.

Infection and skin necrosis, with exposure of the cartilaginous framework, are the most serious complications.

Infection

Infection is the most severe complication as it will be responsible for cartilage resorption. It should be prevented by a very vigorous preparation of the operating field (shaving around the ear, cleaning

the skin invaginations, cleaning of the auditory canal and exposed face and scalp). Cleaning the auditory canal and prescription of antibiotic drops some days before surgery is also helpful. Antibiotics during the operation and postoperative are essential.

When diagnosed, infection must be treated by repeated drainage and appropriate antibiotic therapy. If the infection is serious enough it is usually responsible for resorption of the cartilage, which may in some cases necessitate the carving of another framework.

Skin necrosis

Secondary to a poor blood supply of the skin flaps or excess skin tension over the contours of the cartilaginous framework, skin necrosis is generally due to poor surgical planning. A small exposure less than 2 mm may close by spontaneous healing from the skin edges, which must be cleaned to induce granulation and epithelialization over the exposed cartilage. If a larger exposure needs to be covered, random fascial flaps all around the ear are available, as well as temporal fascia when possible and needed.

Figure 34.14 shows a small exposure that can be managed with correct local treatment, inducing spontaneous healing. When skin necrosis is responsible for a large exposure of the framework (Figure 34.15), a fascial flap can save the situation and must be performed once the necrosis is confirmed, which means some days after the first dressing. Antibiotics must be prescribed after a bacteriologic exam. A random flap of fascia covered with a skin graft harvested on the scalp will save the situation with a good colour match.

Figure 34.17 Ear trauma algorithm.

Too much tension of the skin over the framework can lead to skin necrosis on the antihelix (Figure 34.16). This situation cannot be solved by trying to approximate the skin edges with sutures. Only a short temporal fascia with axial vascularization (ATS) can solve the problem and avoid secondary infection and resorption of the cartilage.

Algorithm

It is essential when reconstructing an ear after trauma to have in mind the principles and guidelines of this surgery. It can be useful to follow a precise algorithm, such as the one shown in Figure 34.17, established by the senior author after three decades of experience in ear reconstruction, including 654 reconstructions after traumatic amputation.

CHAPTER 35

Scalp and calvarial reconstruction

Christopher Glenn Wallace and Fu-Chan Wei

Department of Plastic and Reconstructive Surgery, Chang Gung Memorial Hospital, Chang Gung University, Medical College, Taipei, Taiwan

Introduction

The position of the scalp makes it susceptible to environmental and traumatic injury. It is a common location for skin cancers, as it is normally exposed to solar radiation. The scalp is also a common target of assault with blunt or sharp weapons aimed at inflicting head injury. Hair, particularly if long and untied, is susceptible to entanglement in unguarded machinery, leading to devastating scalp avulsion. Composite defects spanning the calvarium to expose the dura and its content, such as from neurosurgical resections, generally require microsurgical free tissue transfer. The scalp, therefore, deserves special mention with regard to its reconstructive principles, underscored by a clear understanding of its anatomy and aesthetic requirements, including hair restoration. The forehead is considered separately.

Anatomy of the scalp

Borders

Classically, the scalp comprises the forehead as well as the hair-bearing scalp. The borders of the scalp, so defined, are the supraorbital ridge anteriorly, the nuchal line posteriorly and, bilaterally, a line passing through the mastoid process, zygomatic arch and zygomatic frontal process. The frontal hairline separates the forehead from the hair-bearing scalp. Surgically and aesthetically, the scalp refers to the hair-bearing scalp, which is the focus of this chapter.

Layers

These can be remembered by the mnemonic, 'SCALP': skin, connective tissue (or, alternatively, subcutaneous tissue), aponeurosis, loose areolar tissue and pericranium. The skin is thick, hair-bearing and sebaceous. The connective tissue comprises fat and fibrous septa that anchor the skin firmly to the underlying aponeurosis. Traversing the scalp, predominantly within the connective tissue layer, are sensory nerves and a network of arteries and veins. Aponeurosis refers to the galea aponeurotica

(or epicranial aponeurosis), which is a thin, tendinous sheet that unites the paired frontalis and paired occipitalis muscles, and extends bilaterally to the extrinsic auricular muscles. The galea is continuous with the temporoparietal fascia bilaterally and the superficial musculoaponeurotic system (SMAS) of the face.¹ The loose areolar tissue connects the galea to the pericranium and transmits valveless emissary veins between the superficial venous system of the scalp, the diploic veins of the cranial bones and the intracranial venous sinuses. The loose areolar tissue allows the skin, connective tissue and aponeurosis layers to move freely as one unit over the pericranium, such as under the influence of the occipitofrontalis musculature. The pericranium refers to the periosteum of the cranial bones; this is continuous with the endosteum, which lines the inner surface of the cranial bones, at the cranial sutures. The pericranium fuses with the deep temporal fascia bilaterally at its origin from the superior temporal crest.

Arterial supply

The scalp is supplied by the paired supratrochlear, supraorbital, superficial temporal, occipital and posterior auricular arteries; all terminally anastomose to form a rich vascular plexus that connects the internal and external carotid systems and bleeds profusely when injured. These arteries ultimately course predominantly within the connective tissue layer.

The supratrochlear and supraorbital arteries are terminal branches of the internal carotid artery. The supratrochlear artery exits the orbit at its medial angle by piercing the orbital septum and continues vertically over the supraorbital ridge, via its notch (in more than 97%) or foramen,² up the forehead and into the scalp. Within the forehead, it pierces the loose connective tissue and aponeurosis layers to reach the connective tissue layer. It can be located at the supraorbital ridge within 3 mm (mean 0.8 mm; standard deviation ± 0.7 mm) either side of a vertical line passing through the medial canthus; it tends to lie medial to the medial canthus in females and lateral to the medial canthus in males.³ An alternative surface landmark is the glabellar frown line on each side, which the artery passes directly

under in 50% of cases and an average of 3.2 mm lateral to in the remainder.⁴ The supraorbital artery exits the orbit lateral to the supratrochlear artery by piercing the orbital septum and passes over the supraorbital ridge, via its notch or foramen,² up the forehead and into the scalp. Within the forehead it pierces the loose areolar tissue and aponeurosis (through the frontalis muscle) layers to reach the connective tissue layer. It is located by palpating its pulse immediately superior to its notch/foramen, which is usually also palpable.

The superficial temporal, occipital and posterior auricular arteries are branches of the external carotid artery. The superficial temporal artery ascends vertically immediately anterior to the auricle enveloped by the temporoparietal fascia. It divides approximately 3–5 cm superior to the zygomatic arch into its parietal and frontal branches. The pulse of the superficial temporal artery (and its main branches) is readily palpable. The occipital artery ascends from the apex of the posterior triangle of the neck towards the vertex of the skull. Its pulse is readily palpable approximately 3–4 cm lateral to the external occipital protuberance. The posterior auricular artery ascends in the groove between the auricle and the mastoid process. It branches to form anastomoses mainly with the superficial temporal artery.

Venous drainage

The supraorbital and supratrochlear veins accompany their arteries before uniting, medial to the orbit, to form the facial vein. The superficial temporal vein accompanies its artery until it unites with the maxillary vein within the parotid to form the retromandibular vein. The occipital vein usually drains into the suboccipital venous plexus, which continues into the vertebral veins; less often it drains directly into the internal jugular vein. The posterior auricular vein unites with the retromandibular vein as it exits from the parotid to form the external jugular vein. These veins anastomose with each other and with the emissary veins.⁵

Lymphatic drainage

Knowledge of lymphatic drainage patterns is important when treating cancers of the scalp. The lymphatic system is located principally within the subdermal and subcutaneous levels, with drainage to the parotid glands, the preauricular, postauricular, upper cervical and occipital lymph nodes.

Motor nerves

The frontal (also termed temporal) branch of the facial nerve exits the parotid gland approximately 2.5 cm anterior to the tragus, ascends on the periosteum of the zygomatic arch, then continues adherent to the deep surface of, and eventually within, the temporoparietal fascia towards a point approximately 1.5 cm lateral to the orbital rim. It terminates within the ipsilateral frontalis muscle, which it innervates. Injury to the frontal/temporal branch causes ipsilateral frontalis muscle paralysis and progressive brow ptosis. Typically the orbicularis oculi continues to function due to secondary innervation from the

zygomatic branches. According to Seckel, the frontal/temporal branch of the facial nerve lies within Facial Danger Zone 2 on the immediate undersurface of the temporoparietal fascia/SMAS layer. This zone is located within a triangle bound by three lines: (a) a line drawn from a point 0.5 cm below the tragus to a point 2 cm above the lateral eyebrow; (b) a line drawn along the zygomatic arch to the lateral orbit; (c) a line dropped from the first line, to the lateral limit of the eyebrow, to the second line.⁶ Dissection, especially within this zone, should be either superficial to the temporoparietal fascia/SMAS layer or purposefully deep to it, but not immediately beneath the layer. Finally, the occipitalis and extrinsic auricular muscles are supplied by the posterior auricular branch of the facial nerve, which leaves the facial nerve before it enters the parotid.

Sensory nerves

The paired supratrochlear, supraorbital, zygomaticotemporal, auriculotemporal and lesser occipital nerves provide sensation to the scalp and can be blocked with local anaesthetic.^{7,8} The supratrochlear nerve accompanies its artery, providing overlying sensation to conjunctiva, upper eyelid, nasal sidewall, medial forehead and scalp back to the vertex. It can be blocked with local anaesthetic by field-injecting just lateral to the root of the nose at the medial portion of the orbital rim. The supraorbital nerve divides into superficial and deep branches as it exits its foramen to provide sensation, respectively, to the forehead and frontoparietal scalp. It is effectively blocked with local anaesthesia after it exits its palpable notch/foramen. Alternatively, both the supraorbital and supratrochlear nerves can be blocked with transverse infiltration at or slightly above the eyebrow. The zygomaticotemporal nerve provides sensation to the temple and can be blocked by infiltrating just inferoposterior to the zygomaticofrontal suture, which is palpable. The auriculotemporal nerve accompanies the superficial temporal artery anterior to the auricle and supplies the lateral scalp and part of the anterior surface of the auricle. It is effectively blocked with infiltration of local anaesthetic anterior to the auricle. The lesser occipital nerve provides sensation to the lateral occipital scalp and part of the posterior surface of the auricle. It is included within the superficial cervical plexus block, which is performed with field infiltration at the midpoint of the posterior border of the sternocleidomastoid muscle.⁹

Reconstructive principles

The principles of scalp reconstruction are to provide stable and durable coverage (sensate if possible) with aesthetically pleasing contour and hair growth. Although the entire hair-bearing scalp is grossly considered as one aesthetic unit, closer inspection reveals subdivisions in the pattern, density and direction of hair growth. Displacement of aesthetically important neighbouring structures (particularly the anterior hairline, sideburns, eyebrows, upper eyelids and auricles) should be avoided.

Healing by secondary intention

Not every patient with a scalp defect requires surgery. The scalp's good blood supply and high density of skin appendages, when they are intact, contribute to its dependable wound healing. Limited partial-thickness wounds, such as superficial burns or abrasions, may therefore be treated simply with cleaning and dressings. It may be necessary to shave some of the scalp in order to reduce the risk of wound colonization/infection and to improve the adherence of dressings. Deeper partial-thickness burns may still heal with dressings alone, but scar contracture and sparse hair growth may result; these issues can be addressed secondarily if necessary. Full-thickness defects generally require surgical intervention, as discussed below. However, in frail patients, limited exposure even of the outer table of the calvarium can be allowed to granulate secondarily under appropriate moist conditions, owing to its membranous bony origin.

Primary closure

Acute scalp wounds without loss of tissue can generally be debrided and closed primarily. Whenever possible, the galea should be approximated as a separate layer to reduce the wound tension endured by the overlying skin. The abundant blood supply to the scalp allows somewhat tensioned closures for small (up to 2–3 cm width) areas of tissue loss, particularly in the parietal region where scalp mobility is greater. Scoring of the galea aponeurotica perpendicular to the desired direction of skin advancement (without damaging the vasculature lying superficial to the galea) can help, but wide undermining may still be necessary to recruit tissues adequately. It should be noted, however, that if a tension-free closure is not achieved, the scar will likely widen over time and suffer scar alopecia. Even if such approaches render suboptimal aesthetics, they may still be used to achieve wound healing first before definitive aesthetic reconstruction is planned.

Skin grafting and adjunctive techniques

Skin grafts can take on any exposed layer of the scalp that is vascularized and clean. They are particularly useful for resurfacing soft tissue defects such as from resection of skin cancers, as monitoring for evidence of local recurrence over the subsequent years is made easier by the adherence of the graft to the native wound bed. A counterargument is that skin grafts are unable to restore the contour or hair of the scalp, which can be aesthetically displeasing.

Skin grafts can take on freshly burrered calvarial outer table as long as the conditions are appropriate for wound healing to progress. However, such reconstructions are fragile and tend to undergo repetitive wound breakdowns and regranulations; they are also aesthetically poor. Skin grafting directly onto calvarial bone should therefore be reserved for patients who are unsuitable for, or refuse, anything more complex. Prior to application of the skin graft, the calvarial bone should be seen to produce pinpoint bleeding points. Alternatively, the outer table can be

removed to reveal the well-vascularized diploic space,¹⁰ or a pericranial flap designed to cover the bone before grafting; however, these options are more morbid and still provide poor aesthetics, thus inviting other options to be considered instead.

Negative pressure dressings can be applied to improve graft take or encourage granulation,¹¹ and dermal substitutes can be useful to improve the quality of skin graft reconstructions.¹⁰ It is also possible to transplant hair to skin-grafted scalp that has appropriate underlying soft tissues. Ultimately, however, a successful hair-bearing reconstruction would be an aesthetic improvement on most skin-grafting techniques. Like a tensioned primary closure, skin grafting can sometimes be useful to achieve wound healing, and a definitive aesthetic reconstruction can be performed at a later stage, if necessary, once the wound is quiescent.

Local flaps

Local hair-bearing flaps are useful when recruitment and advancement of neighbouring tissue cannot achieve a tension-free closure. Although a plethora of locoregional flap techniques have been described for use on the scalp, the most dependable options are variations of rotation and transposition scalp flaps. Single transposition flaps generally require a skin graft for the secondary defect, so rotation scalp flaps should be preferred when available. If the donor site of a rotation flap is predicted to require grafting, consideration should instead be given to tissue expansion first if a multistaged reconstruction is feasible and acceptable.

Pinwheel flaps are useful for small circular defects. They incorporate a series of random pattern rhomboid flaps bordering the defect, each designed to reconstruct one sector of the defect and achieve donor site primary closure. They are an alternative that avoids the long curvilinear incisions required for scalp rotation flaps and are able to replace hair-bearing scalp with like tissue.

A recipient defect in an advantageous location on the scalp (i.e. placed laterally rather than centrally) of up to a maximum of approximately 5–6 cm diameter can be closed with a primarily closed large scalp rotation flap that is both scored then back-cut. These need to be designed with an axial pattern blood supply, incorporating at least one of the named arteries of the scalp. Ideally, the flap should be at least 5 times wider than the diameter of the defect to allow wound closure with acceptable tension; hence even a 5 cm circular defect can stretch the limits of a scalp rotation flap with a primarily closed donor site. Meticulous reverse planning with careful attention to pivot point, blood supply, sensory supply and defect/flap dimensions are critical. The long curvilinear incision is performed with a scalpel, employing electrocautery only sparingly for specific bleeding points to reduce damage to hair follicles; the subgaleal plane is used to raise the flap widely. If skin grafting is to be employed, the donor site should preferably be left with undamaged pericranium and located inconspicuously or so that it can be camouflaged with hairstyling.

Although the pericranial, pericranial–galeal and temporalis flaps can be useful for small defects with exposed dura or exposed dural repair, in the setting of scalp reconstruction, such problems may be better addressed instead with free tissue transfer. It should also be noted that Orticochea's oft-referred-to descriptions of three-flap or four-flap scalp reconstructions are of historical interest only. They were useful for defects over the occipital scalp and involved extensive scoring of the galea to maximize flap advancement. They brought high risks of postoperative alopecia, unnatural direction of hair growth, wound-healing problems and the requirement for skin grafting, but were an ingenious solution to difficult scalp defects prior to the wider availability of tissue expansion and free tissue transfer. Likewise, free tissue transfer has replaced many of the regional flap options, such as the pedicled latissimus dorsi and splenius capitis muscle/myocutaneous flaps, in the remit of scalp reconstruction. The trapezius myocutaneous flap, however, is a reasonable option for moderately sized composite occipital scalp ablative defects for which tissue expansion would be contraindicated by the presence of tumour.

Tissue expansion

Immediate expansion can be achieved intraoperatively with traction applied to the skin edge. The biological principles and application of tissue expansion is covered in Chapter 6 in this book. Briefly, removal of the traction causes the skin to relax to its original dimensions. If the applied load is excessive, however, the skin stretches without subsequent relaxation. This can be exploited when advancing local tissues as long as tissue perfusion is maintained under the applied tension; otherwise the sutured leading edge will become ischaemic, necrose and the wound will dehisce. Tissue creep instead occurs over time under constant loading, such as from placement and expansion of a

prosthetic tissue expander. Mechanical creep involves the stretching and alignment of collagen fibres, microfragmentation of elastin, and the displacement of interstitial fluid, whereas biological creep involves the generation of new tissue. With progressive tissue expansion, the epidermis thickens due to cellular hyperplasia, the dermis thins, appendages spread, and fat and muscle layers thin. These properties can also be exploited for serial excision of moderate-sized benign lesions of the skin.

Tissue expansion of the scalp allows the replacement of like with like tissue that is both hair-bearing and potentially sensate (Figure 35.1). The intention is generally to expand a scalp rotation-advancement flap in order to allow defect coverage as well as donor site primary closure. Judicious planning, especially the placement of expander pockets, ports and incisions, is key to reducing morbidity. General guidelines for tissue expansion in the head and neck region include the following:

- Choose a tissue expander with a length and breadth that is at least as large as the defect.
- Design the incision perpendicular to the direction of intended expansion, make it as small as possible, and locate it away from the defect, the pocket and the future flap incisions.
- Place the valve in a healthy area above and/or lateral to the expander, and at least 7 cm away.
- Fill the expander at the conclusion of the operation in order to reduce seroma/haematoma and the need for drains.
- Wait two weeks for healing before beginning expansion, and continue weekly thereafter.
- The capsule can be incised to increase stretch, but avoid a full capsulectomy.
- Elasticity and contractility of the expanded flap depend on individual factors, but an estimation of gained flap length is the distance over the dome of the expander minus the corresponding measurement of its base.

Figure 35.1 (a) Alopecia in the occipital region treated with a tissue expander. (b) Postoperative appearance at two months. Source: Dr Shiow-Shuh Chuang. Reproduced with permission.

- With this measurement in mind, overexpand by 30–50% to account for flap contraction, as the theoretical flap gain is rarely, if ever, yielded *in vivo*.¹²

Multiple tissue expanders can be employed when more than one expanded flap is necessary or when a large flap requires expansion in different areas. Although the direction of hair growth on a rotation-advancement scalp flap is unlikely to match perfectly the neighbouring uninvolved scalp, every effort should be made to inset the flap in such a way as to minimize this disparity.

Microsurgical free tissue transfer

Free flaps are useful when there is an absence of healthy local tissues (for example, due to irradiation, extensive scarring from multiple previous reconstructions, neighbouring trauma), and when the surface area of the defect is too large for local flap reconstruction or is composite (spanning the calvarium or more deeply). Microsurgical free tissue transfer can offer a single-stage solution for extensive scalp defects, which is particularly important in the ablative oncologic setting. Free flaps also import fresh, vascularized and healthy tissues from a distant site, which can be the critical factor that allows wound healing in irradiated or previously infected fields. The principle drawbacks of free tissue transfer to the scalp are that these flaps cannot bring the same density of hair and they are generally thicker. The former can be addressed at a later stage with hair transplantation if necessary, and the latter either by primarily or secondarily thinning a cutaneous/fasciocutaneous flap or by importing a muscle flap and sheet skin grafting its surface. The muscle will atrophy and conform over time, producing aesthetic outcomes that can be surprisingly acceptable, particularly if the patient had preexisting alopecia. If, however, the patient were planned for postoperative irradiation, a fasciocutaneous free flap would provide more robust healing of the skin. Sometimes the ablative composite defect spares the hair-bearing skin of the native scalp; in such circumstances, an adipofascial free flap with or without muscle can be de-epithelialized and buried to obliterate the deadspace and restore contour. A small monitoring paddle can be incorporated into the design and later removed under local anaesthetic once its purpose has been fulfilled.

Many free flap donor sites have been described for scalp/calvarial resurfacing, including the latissimus dorsi, rectus abdominis and gracilis muscles or omentum with skin graft, and the cutaneous/fasciocutaneous anterolateral thigh, parascapular/scapular and radial forearm flaps. When the defect is composite, involving the calvarium and/or dura and/or brain, the free tissue transfer can be tailored to incorporate fascia and muscle as required. The anterolateral thigh is probably the most versatile donor site for composite ablative defects (Figure 35.2), allowing vascularized fascia lata to be brought with the flap as a replacement for the dura, voluminous vastus lateralis muscle for deadspace obliteration in cases of neurosurgical ablations, and a long pedicle that is sizeable and dependable. It is also located far from the scalp, which allows a two-team approach during ablative surgery or recipient site preparation.

However, if the requirement is for subtotal or total cranial resurfacing, the latissimus dorsi muscle with skin grafting provides the greatest area for coverage while allowing primary closure of the donor site; the omentum is an alternative large resurfacing flap but requires the abdominal cavity to be breached. An extensive fasciocutaneous free flap would be possible but a less desirable option since donor site skin grafting would be necessary if the subtotal scalp was to be resurfaced. The nearby superficial temporal vessels on either side are dependable recipient vessels for free tissue transfer. Free flaps with long pedicles are necessary to reach alternative recipient vessels in the neck. Eccentric design of the vascular hilum of the flap can effectively lengthen the pedicle but vein grafts may still be necessary when reconstructing defects near the vertex.

Replantation

Scalp avulsion classically occurs from entanglement of loose hair in machinery, but animal bites and 'scalping' assault injuries are other causes. It is important that the patient is aggressively resuscitated with fluid and blood products as necessary and pressure applied to bleeding points as scalp injuries can bleed catastrophically. No reconstructive alternative can provide superior results to scalp replantation and thus it should be attempted whenever possible (Figure 35.3). Mechanical scalp avulsions predictably cleave along the path of least resistance, which is the loose areolar tissue plane between the galea aponeurotica and the pericranium. This means that the axial vascular network supplying the amputated scalp (residing superficial to the galea) may well be intact and allow replantation. Indeed, extensive collateralization of vessels means the entire scalp can be revascularized on one set of anastomoses.

The few contraindications to an attempt at replantation include devastating multitrauma precluding attempted microsurgical salvage and a severely crushed and/or macerated amputate with multiple-level segmental injuries. Even if the scalp is avulsed in more than one part, each sizeable scalp island should be attempted for replantation unless clear contraindications exist.

Preoperative shaving of the entire scalp and amputate leaving approximately 1 mm of hair length allows better appreciation of lacerations/contusions and correct alignment of wound edges. Accurate identification and resection of traumatized vasculature and replacement with vein grafts as necessary is critical to success. Usually the superficial temporal vessels are the chosen recipient vessels, often proximally within the parotid owing to the avulsive segmental vascular injury, however the supraorbital, occipital and postauricular vessels have also been used. The arterial inflow should be restored first both to reduce ischaemia time and to declare at least two high-outflow veins for anastomoses; other veins should be ligated to reduce blood loss. The scalp should then be carefully inspected for regions of threshold perfusion once vascularity is restored as additional anastomoses may be necessary. The use of *hirudo medicinalis* with antibiotic coverage, or alternative chemical/mechanical leeching methods,¹³ should be considered if venous congestion

Figure 35.2 (a) Scalp defect after skin cancer excision. (b, c) Postoperative appearance after anterolateral thigh flap reconstruction.

persists despite multiple flowing venous anastomoses. Failed replantation can be salvaged by negative pressure dressing assisted wound closure,¹¹ skin grafting or microsurgical free tissue transfer, but each of these options provides comparatively poorer aesthetics.

Reducing the risk of scar alopecia

If at all possible, the potential for hair regrowth should be preserved at the index operation. Employing simple measures such as avoiding wound tension and not using electrocautery or crushing instruments at the cut edges of the scalp help reduce the risk of follicular damage and scar alopecia. When performing the incision, some authors report aligning the scalpel parallel with the follicle, whereas others prefer to transect the follicle obliquely. The trichophytic method used by hair transplantation surgeons for strip harvest donor sites involves a combination of these concepts. First, the surgeon takes careful note of the direction of hair growth on either side of a planned incision. In any location on the scalp, there will be one side (Side A) of the incision where the hair grows toward the incision so that the hair shaft overlies it, whereas on the other side (Side B) the hair correspondingly

grows away from the incision and the shaft does not overlie it. Second, the incision is placed with a scalpel blade aligned with the direction of hair growth. As the incision is deepened, it should follow the curvature of the hair shafts so that the follicular components underlying the dermis and bordering the incision are not cut. Third, a trichotomy is performed as follows: the leading edge of Side A is de-epithelialized by 1 mm, resulting in the subepithelial transection of hair shafts bordering the incision on Side A. This leaves the dermal/subdermal components of the hair follicles intact, preserving their ability to continue producing hair. Classically, a trichotomy is not performed on Side B, but some authors believe that doing so further improves scar concealment.¹⁴ Fourth, the incision is closed with fine sutures so that the epithelial edges accurately appose. Accordingly, the hair shafts transected during the third step are directed to grow through the incision and thus within the scar, disguising its presence. Proponents of the technique suggest that the suture used for wound closure, whether single or double layered,¹⁴ should not bite deeper than approximately 1 mm because the bulge of the hair follicle extends between about 1.0 mm and 1.8 mm below the skin surface.¹⁵ These principles can be applied

Figure 35.3 (a) Avulsed scalp. (b) Appearance three months after microsurgical replantation. (c, d) Appearance one year after replantation.

to any incisions and wound closures on the scalp to reduce the risk of distressingly conspicuous scar alopecia.

Hair restoration

Alterations in hairstyling, psychological adjustment and acceptance, preference for wearing hats, or tolerance of wigs, toupées and other camouflages for alopecia, can mean that autologous hair restoration is not always necessary or requested. For those patients who would prefer hair restoration to proceed, the principal techniques used are surgical: tissue expansion, scalp reduction and hair transplantation. For aesthetic restoration purposes, however, tissue expansion and scalp reduction have largely been superseded by follicular unit transplantation. The two medical treatments that are approved by the US Food and Drug Administration for treating alopecia (minoxidil and finasteride) are indicated for generic rather than site-specific alopecia, such as due to male pattern androgenic alopecia.

Hair restoration can dramatically improve aesthetic and psychosocial outcomes for the patient following surgery or other

trauma that has left an alopecic patch, disrupted hairline, scar alopecia or a poorly designed hair-bearing flap inset. Previous punch-graft techniques, which produced unnatural 'plugged' or 'doll-like' appearances, have largely been replaced by highly sophisticated methods of follicular unit harvest, selection, preparation and transplantation into considered patterns and orientations of hair. An in-depth appreciation of the finer points of technique required to produce pleasing outcomes are important; these will only be covered broadly. The reader is directed to a selection of comprehensive review articles covering the meticulous approach necessary at every step for successful follicular unit transplantation.^{16–19} As stated by Rousso and Presti, 'the technique is only as effective as the technician, and results are heavily dependent on the forethought of the architect'.¹⁹ Accordingly, subspecialty training is important, both for the surgeons and their teams, before embarking on this technique.

Broadly, the goal of hair transplantation is to mimic the patient's natural hair growth pattern in an area of alopecia so

that it aligns and blends with its surrounds. This requires a careful analysis of the undisrupted hair, including its colour, density and direction of growth, bordering the area of concern so that its features can be mimicked as closely as possible. The patient's expectations must be appropriately managed and an evaluation of potential donor sites performed and explained to the patient. It should be emphasized to the patient that the donor hair density and calibre are critical determinants of the fullness of the transplanted recipient site. Standardized photography with a light blue background is important for documentation;¹⁸ video is also used to demonstrate the dynamic movement of native and transplanted hair, such as when being combed through.

The donor site for follicular unit transplantation is usually either an occipital strip followed by microdissection of follicular units, or multiple follicular unit extractions performed manually or, more recently, robotically (Figure 35.4).²⁰ The occipital strip should be located horizontally in a region between the

occipital protuberance and 1 cm above the top of the auricles, and trichophytic closure used. Its size is determined by the follicular density in the region, as calculated by hair densitometry, and the predicted number of follicular unit transplantations to be performed. It is critical that follicular units are kept viable once harvested; chilled isotonic saline is one medium that is often used. Single follicular units are microdissected from the occipital strip by skilled technicians and arranged according to how many follicles the unit contains (one to four) so that the surgeon can inset them in an organized and expedient fashion.

The surgeon designs and plans the placement of the follicular units according to the aesthetic requirements of the recipient site. If a hairline is to be restored, this is perhaps the single most important determinant of the final aesthetic outcome. It must be located accurately – broken up by irregularly irregular gaps and triangles rather than linear – and transition naturally and progressively from the non-hair-bearing skin to reach the

(a)

density of the native scalp.¹⁸ Each part of the scalp, such as the anterior hairline, crown and temporal regions, has its own follicular aesthetics that need to be restored for a good outcome. Generally, hypodermic needles, mindi knives or micro-punches are used to create recipient ports for the transplants. These need to be placed with the intended direction of hair growth in mind as well as the correct depth, so that the follicular unit skin sits flush with the recipient site. An evaluation of the transplant result can be performed at approximately eight months when the follicular units have appropriately cycled through their expected telogenic and anogenic phases.

Future considerations

The current array of autologous reconstructive techniques can provide wound closure and healing for the vast majority of scalp defects. However, the outcomes of extensive reconstructions, such as following failed total scalp replantations or full-thickness subtotal scalp burns, are generally not aesthetically pleasing.

Although hair transplantation can improve regions of alopecia, the lack of donor material in total scalp reconstruction is currently an unsolved problem. Efforts continue in basic research and biotechnology company laboratories to find methods of cloning hair follicles for transplantation to be possible with minimal donor material, but results so far have been disappointing.¹⁸

Total facial vascularized composite allotransplantations (VCAs) with scalp extensions have been performed with hair regrowth, facial functional return and excellent aesthetic results.²¹ Cadaveric work allows opportunities for planning total facial VCAs that incorporate total scalp and avoid facial cutaneous scars.²² Additionally, clinical cadaveric scalp VCA, allotransplantation of muscle in an already immunosuppressed patient, and scalp flap transplantation between identical twins have all been reported for scalp reconstruction.^{23–25} For the moment, however, scalp VCA is only justified when performed as an extension of a facial VCA, given the inherent lifelong risks of immunosuppression.

Conclusions

The scalp commands an important influence on the overall aesthetics of the face and skull and considerable psychosocial morbidity can result from suboptimal scalp reconstructions and/or alopecia. The presented techniques offer acceptable reconstructions for the vast majority of scalp defects and non-hair-bearing reconstructions can be improved with follicular unit transplantations or well-designed pre-expanded scalp flaps. Wound healing can be achieved for total scalp defects, but hair restoration remains a problem when there is no donor material present.

CHAPTER 36

Facial trauma

David David

The Australian Craniofacial Unit, Adelaide, Australia

Frontal bone and naso-orbital fractures

The frontal bone and naso-orbital region constitute the upper third of the face. Trauma to this region of the face is often accompanied by brain injury and damage to the cranial nerves. The impacting forces may be transmitted to the base of the skull, producing a range of effects from transient loss of consciousness to loss of life. The injuring force may impact directly on the frontal bone, causing blunt or penetrating brain injury. With this in mind, it becomes obvious that the treating surgeon should be part of a team capable of assessing and treating such injuries.¹ The injuries therefore fall into three categories: injuries to the bone without cerebral involvement, externally compound fractures or penetrating wounds with underlying dural and cerebral injury, and internally compound fractures often of the cribriform plate region resulting in a cranionasal fistula with or without cerebrospinal fluid (CSF) leak.

Some of the causes of craniofacial trauma include falls, assaults, sporting injuries, industrial accidents and missile injuries. The epidemiology varies with the community so when organizing multidisciplinary care and planning preventative strategies, an understanding of the causes and incidences in a particular community is essential.²

Anatomy

The anterior cranial fossa is formed in the front and at the sides by the *frontal bones*, and they are attached to the facial skeleton at the front nasal, frontomaxillary and frontozygomatic sutures (Figure 36.1). The frontal bone also articulates with the ethmoid bone in the anterior cranial fossa, which bone forms part of the orbit and its vertical plate forms part of the nasal septum and indeed is said to play a part in facial development. Laterally, the anterior fossa forms the thin superior orbital plates; they dip down medially to articulate with the cribriform plate of the ethmoid, the posterior articulation of which is the body of the sphenoid bone. The lesser wings of the sphenoid bone form the

crescentic posterior borders of the anterior fossa. The optic canal is formed by the two roots of the lesser wing of the sphenoid and runs forward and laterally in the superolateral wall of the sphenoid sinus to the orbital apex.

The complex sphenoid bone is the keystone of the craniofacial skeleton; it forms part of the anterior cranial fossa, the middle cranial fossa, the lateral orbital wall, where its articulation with the zygoma is an important landmark in the reduction of orbitozygomatic fractures, and the infratemporal fossa.

The rest of the facial skeleton is composed of the lacrimal bones, the nasal bones, the ethmoids, the zygomas, the maxillae and the mandible. It is customary to describe the face as being divided into three thirds. The upper third is formed mostly by the frontal bone, which forms the orbital rooves. The middle third contains the maxillae, zygomas and the nasoseptal complex with a contribution from the lacrimal bone and the ethmoid. These elements articulate laterally with the zygomatic processes of the temporal bones, and serve as a good measure of the anterior projection of the face. Posteriorly they articulate with the sphenoid to form the orbit and centrally and laterally with the frontal bone. The lower third is said to be formed by the mandible, however this is somewhat of a convention as the body only is in the lower third, the ramus in the middle third and the temporomandibular joint has a major component formed by the base of skull.

The midfacial skeleton is designed to transmit the powerful forces of mastication to the base of skull. The horizontal elements in the maxilla, the alveolus and hard palate support three paired vertical buttresses, at the pyriform margins at the zygomatic maxillary junction and more posteriorly at the pterygo maxillary junction. The two pairs of anterior buttresses provide the best places for internal fixation with plates and screws.

The *orbital cavity* is formed of seven bones in the shape of a four-sided pyramid. There is a relatively strong rim anteriorly, four more flimsy walls and a thick apex. The zygoma contributes to the lateral and inferior orbital margins, the lateral orbital wall and the orbital floor. The maxillary component of the orbital floor medial to the zygoma is thin and delicate (lamina papyracea).

Figure 36.1 A transilluminated adult skull demonstrates the paranasal sinuses and the supporting buttresses of the face.

The anterior orbital floor medial to the infraorbital canal is concave downwards, but posterior to the globe it becomes convex upward. A point to be noted for successful restoration of the orbital floor after injury: the medial wall is composed of the lacrimal bone anteriorly and the thin lateral plate of the ethmoid posteriorly.

The *paranasal air sinuses* are rudimentary at birth and do not reach adult proportions until puberty. The degree of pneumatization varies, particularly that of the *frontal sinus*. They range from being barely pneumatized to extending superiorly in the frontal bone for a variable distance; laterally they can go as far as the lateral margins of the orbit and also extend into the orbital roof.

The frontonasal ducts open inferomedially and drain into the frontal recess of the nasal cavity.

The *ethmoid sinuses* constitute an interconnected series of thin-walled cells that lie between the upper lateral nasal cavity and the orbit and are separated from the orbit by the thin lateral wall. Their roof forms part of the anterior fossa lateral to the cribriform plate. The ethmoid sinuses are related to the maxillary sinuses inferiorly, the frontal sinuses superiorly, and the sphenoid sinuses posteriorly.

The *sphenoid sinuses* are within the body of the sphenoid and may sometimes spread into the lesser wing of the bone; they are divided by a septum and may be asymmetrical. They lie under the central part of the floor of the anterior fossa and are closely related to the internal carotid artery, the pituitary gland and the optic nerve. They connect through their anterior wall with the upper nasal cavity.

The *maxillary sinuses* usually fill the entire body of the maxilla and may extend into the zygoma and below the floor of the nose; their walls are fragile and easily broken. They also are rudimentary at birth.

Management principles

Management involves investigation and treatment and should be based on a thorough knowledge of the *pathophysiology*.

With respect to the *cranial cavity* the dura is firmly attached around the cribriform plate through which the filaments of the olfactory nerve pass sheathed by arachnoid. A dural arachnoid tear with a fracture communicating with the nose or paranasal sinuses will lead to CSF leak.

The frontal lobes of the *brain* are particularly vulnerable to the effects of frontal impact, and by anterior fossa fractures when the orbital rooves are shattered or buckled. Bilateral frontal lobe injury can result in long-term neuropsychological problems.

The *olfactory nerve* filaments may be damaged by fractures crossing the cribriform plates resulting in anosmia as well as CFS leak.

The *optic nerve* may be compressed by a displaced fracture through the optic canal, by shearing forces that devascularize the nerve, by contusion or haematoma within the canal without a fracture, or by direct injury to the orbit.

The *orbit* itself may be fractured directly or indirectly as part of frontal, nasoethmoid and midface or zygomatic fractures.

In addition to the pathophysiology, it is essential to have knowledge of the effects resulting from the various *mechanisms of injury*.

Frontal impact is the most common mechanism of craniofacial injury; it may result in linear fractures or depressed fractures, and the forces may be transmitted to the cranial base and cause fracturing there.

Fractures of the skull base are rarely significant in themselves, however the force required producing such a fracture is considerable and is often associated with injuries of the soft tissues, brain, cranial nerves, major vessels, etc.

The pattern of fracture lines resulting from blunt trauma follows the points of weakness and in the frontal bone is influenced by the extent of the frontal sinuses and the particular honeycomb structure of the particular sinus (Figure 36.2). The age of the patient is a significant influence, younger bones being more pliant and less brittle. Fracture patterns, however, rarely conform to a predictable formula.

Penetrating and missile wounds have no particular pattern. The tissue damage resulting from low-velocity penetration is confined to the pathway of the penetrating agent.^{3,4}

Figure 36.2 (a) CT scan showing a depressed comminuted fracture of the frontal sinus affecting both inner and outer tables resulting from blunt trauma. (b) A fracture of the orbital roof resulting from a billiard cue entering the orbit, sparing the globe, and penetrating the orbital part of the frontal bone and brain.

Gunshot wounds may be penetrating, perforating or ablative depending on the velocity and nature of the projectile, the higher the velocity, the greater the damage. High-velocity missiles cause massive avulsion with loss of bone and soft tissue, which is often more extensive than immediately apparent because tissues may be devitalised or injured by the traction of avulsion. The eyes and brain may be injured directly or by vascular injury, which can be delayed.⁵

Crushing injuries may result in severe fracturing of the frontal bone and skull base; however in infants and children the pliability of the bones means that the pattern of fracture is different with greenstick fractures.⁶

Initial management

Remember to save the patient! Fractures of the frontal bone and nasoethmoid complex can occur in isolation but more commonly are associated with other facial and systemic trauma. Severe craniofacial injuries often pose an immediate threat to life. Airway obstruction, displaced dentures and collapse of the mandibular arch with retro displacement of the tongue may cause severe hypoxia. Particular care should be taken with cases of frontofacial fractures, where the possibility of a breach in the anterior cranial fossa exists, not to forcibly insufflate the patient or to pass tubes via the nose.

Emergency assessment and resuscitation

The primary survey, setting the priorities for management, follows resuscitation, secondary survey and stabilization, and in the craniofacial region these are: airway, breathing and circulation.

Airway

The following is a list of problems that may be encountered when trying to secure the airway in severe frontofacial fractures. Subsequent chapters deal with fracturing of other regions of the face, and these same problems potentially occur.

- Distortion of the bony facial skeleton
- Swelling of the lips, tongue and floor of mouth
- Broken teeth and dentures
- Multiple fractures of the mandible with loss of tongue support
- Haemorrhage into the soft tissues of the neck hindering cannulation of the airway
- Disruption of the anterior cranial fossa
- Trismus
- Blood and vomit in the airway
- Fracture of the larynx.

Breathing

Associated chest injuries must be excluded. A brain injury may cause central problems with breathing as can the overzealous or inappropriate use of pain relief.

It therefore behoves the treating team to assess and secure the airway safely and soon. This may be difficult and intubation requires a skilled and experienced anaesthetist. Nasal intubation in patients with fractures potentially involving the anterior base of skull should be undertaken with great care. There are various anaesthetic strategies to minimize the risks.

Tracheostomy in an awake patient under local anaesthesia may be considered, however if the neck tissues are suffused, cricothyroidotomy can be used.

Circulation

Craniofacial injuries, especially those of the midface, can involve severe bleeding from the branches of the external carotid artery that supply the region. Superficial arterial bleeding may be controlled

by pressure or by wound exploration and ligation of the bleeding vessel. Packing may control bleeding from the nasal cavity or oropharynx. In the rare case when this cannot be achieved, arterial ligation may be considered, the maxillary artery via a transantral approach and/or ligation of the anterior ethmoidal artery, which is a branch of the internal carotid system and enters the orbit through the medial orbital wall. Interventional radiological techniques are emerging as useful tools in controlling deep bleeding in this area.

Clinical assessment

This assessment applies to all fractures of the craniofacial skeleton and precedes the special investigations.

The *neurological state* should be determined early using the Glasgow Coma Scale to record consciousness. It is necessary to examine the cranial nerves, and careful ophthalmological assessment may lead to urgent consultation with an ophthalmologist. Testing for light touch in the various zones identifies facial sensory nerve function. The facial nerve is tested by observation and by response to painful stimuli.

The *face* should be examined for lacerations and contour deformities. Bruising around the orbits may indicate an anterior fossa fracture, and bruising around the mastoid process indicates a temporal bone fracture. CSF leakage should be suspected, but in the presence of blood and mucus it is very hard to identify with certainty at this early stage.

Jaw movements and the muscles of facial expression are tested; the cervical spine is palpated for tenderness or deformity and the scalp for lacerations and haematomas.

Each facial region should be palpated systematically from the frontal bone to the mandible, looking for evidence of deformity or abnormal movement. Cooter⁷ has described a systematic sequence of examination by palpation.⁸ Palpation of the inferior orbital margin may help differentiate isolated fractures of the zygoma where the lateral rim is depressed from nasomaxillary fractures where the medial rim is depressed.

The mandible is examined with the patient's mouth slightly open; the margins of the bones are palpated externally. Intraorally, with a gloved finger the alveolar ridges and the hard palate are palpated. Grasping the maxillary alveolar ridge or pressing on the anterior hard palate behind the teeth and applying a rocking movement while palpating the face with the other hand can elicit abnormal movements of the midface.

Imaging

Early imaging

- *Computed tomography:* A cranial CT is performed after the initial resuscitation to assess for possible brain injury. It may be extended to include other areas of suspected injury. Fractures of the anterior fossa may warrant fine-cut bone windows at this stage, but it is the later investigations that will give the definitive information.

- *Angiography:* At this stage, angiography is indicated for penetrating injuries in the region of major vessels or blunt injuries where there is suspicion of vascular damage.

Later imaging

The detailed diagnostic imaging is usually planned after full clinical investigation is complete. It has become regular practice for the first and principal investigation to be a CT scan, however some of the standard radiographic projections can be most useful and in some circumstances essential (e.g. the panoramic radiograph (orthopantomogram, OPG) that shows the mandible, temporomandibular joints and teeth).

Axial CT scanning is vital in managing severe craniofacial trauma of the frontal and nasoethmoid region. Fine-cut two-dimensional CT is the best method for assessing craniofacial fractures around the fronto-orbito-ethmoid region and the fractures are seen most clearly on the scan at right angles to the bone that is fractured. The acquired CT slices, usually axial, can be used to produce a three-dimensional image of the skeleton and/or soft tissues. These images can be rotated and viewed from all angles and are indispensable for surgical planning. These data can be used to create solid nylon models of the injured skull, which can be sterilized and used for reference at surgery or for mock surgical planning.⁹

MRI is often useful later in tracking the origins of CFS leakage. It is used to assess ocular injuries and also to identify non-metallic foreign material, especially wood.

Definitive management

Having resuscitated the patient, established the presence of brain injury, established an infection control regimen and made a clinical and radiological diagnosis, the next step is to establish the priorities in managing the craniofacial injury, in this case the frontal and naso-orbital fractures. Urgent surgical intervention within hours is indicated by the presence of acute neurosurgical problems of intracranial bleeding, penetrating brain injuries or externally compound fractures. Otherwise delayed treatment is preferred by an appropriate team after full investigation and planning in the 'cold light of day'.

Urgent operative intervention may be necessary for injuries to other body systems, and appropriate discussions will determine what parts of the management can be done simultaneously.

Operative surgical principles

Modern craniofacial surgical technique is based on wide exposure of the craniofacial skeleton, the capacity to reduced bony fragments precisely and implement rigid inter fragmentary fixation with titanium mini- and microplates. Where there is absence of bone from the trauma, primary bone grafting of defects is undertaken at this stage.

The most effective and commonly used approach to the naso-orbito-frontal region is the *coronal scalp flap* (Figure 36.3). The incision is placed well behind the hairline and is made in a wavy or zigzag fashion to better disguise the scar. The flap is raised in

the subgaleal plane down to a level about 2 cm above the orbital margins or the site of any fractures of the frontal bones. The dissection then proceeds subpericranially, scraping the bone and extends over the orbital rim into the orbit. The supraorbital neurovascular bundle is preserved and, if necessary, chiselled out of its canal. More medially, the dissection disconnects the trochlea without obvious deleterious effect.

Laterally, it is important to dissect strictly against the temporal fascia beneath the fatty layer directly superficial to it in order to preserve the frontalis branch of the facial nerve. Within the orbit the periorbita may be safely dissected to within 1 cm of the apex, however in traumatic cases the walls may be breached, the periorbita torn and orbital fat trapped in fracture lines, making dissection more difficult.

Medially, in the region of the glabella, the dissection can be taken down over the nose, anteriorly and posteriorly to the canthal ligaments and nasolacrimal ducts. These structures, so often injured, must be identified and preserved.

Access to the anterior part of the medial orbital wall can be obtained via a transcaruncular approach. The floor is exposed by subciliary eyelid incisions or best by transconjunctival incisions with or without lateral canthotomy.

Bone grafting

Bone loss demanding early replacement can occur over the frontal sinus, in the orbital walls, especially medial, and the floor, and after comminuted depressed fractures of the nasal pyramid. In the middle third of the face the vertical bony pillars may need to be grafted to secure midfacial height.¹⁰

The common donor sites for harvesting bone are the iliac crest and medial surface of the ilium, the ribs (both bone and cartilage) and the calvaria. The most important factors

for the survival of bone grafts are: rigid fixation, good soft tissue coverage, a well-vascularized bed and absence of haematoma.

There is a wide selection of all plastic materials to reconstruct the midface and orbits, none of which are favoured by this author. In particular their use in relation to open sinuses should be avoided.

Donor sites

Hip grafts provide strong malleable bone (Figure 36.4). The inner table can be harvested, and additional cancellous bone scooped out for packing (e.g. the nasofrontal duct). The full thickness of the ilium can be used but it is important to preserve the crest in both adults and children.

Rib grafts are harvested through a submammary incision, cartilage can be taken in the form of the costochondral junction for use in the nose and the temporomandibular joint. Ribs can be used whole or more usually split for calvarial or orbital reconstruction (Figure 36.5).

Figure 36.3 A zigzag or wavy coronal incision gives a better final scar. The flap is raised over the pericranium and superficial temporal fascia. The pericranium is incised 1 cm superficial to the superior orbital margin and the dissection continued subperiosteally into the orbit. Staying deep to the fat pad over the superficial temporal fascia will protect the frontalis branch of the facial nerve.

Figure 36.4 A graft taken from the inner table of the right hip.

Figure 36.5 Rib with attached costal cartilage can be used to support the crushed nasal dorsum.

Calvarial grafts have the disadvantage of being less malleable than hip or rib grafts. Small portions can be taken from the outer table where the skull is thick enough, obviating a need for extra visible scars, however contour defects or the skull are often a problem as are complications arising from damage to the underlying dura and brain arising from inexperienced operators. The inner table can be harvested when a craniotomy is being performed and the bone is thick enough. Good quantities of high-quality bone can be obtained in this fashion (Figure 36.6).

Operative management

This depends on the nature of the fracture pattern. Each case must be managed on its merits but there are a number of consistent and significant variations, such as:

- a fracture of the outer table of the frontal sinus with skin intact and a contour defect of the forehead;
- a compound fracture with the outer table involvement as above;
- a compound depressed fracture involving the anterior and posterior walls with suspected involvement of dura and brain; and
- depressed fractures of the frontal bone lateral to the sinus with or without involvement of the orbital roof.

Penetrating wounds need separate consideration due to the extreme risk of contamination.

The *simple depressed fracture* with a contour defect can be approached via a coronal flap; the fragments can be repositioned and secured with microplates or fine wires. If there is an overlying or adjacent wound this can be debrided and the same procedure undertaken.

A *compound depressed fracture involving both walls* is also approached through a coronal scalp flap (Figure 36.7). A small frontal craniotomy is made above the sinus area to expose the posterior wall, the depressed fracture being approached extradurally. If the dura is torn, the posterior

wall of the sinus is nibbled and drilled away (cranialized) and the sinus mucosa meticulously stripped. The dura is repaired in a watertight manner by primary suture and may be augmented by a graft of temporalis fascia or pericranium (Figures 36.8, 36.9 and 36.10).

The *frontonasal duct* can be plugged with muscle and/or bone chips. A pericranial flap pedicled inferiorly is turned in and sutured to the dura in order to seal the frontal sinus. The anterior wall of the sinus is preserved and, if fragmented, treated as in the case of a simple depressed fracture.

Closed anterior and posterior wall fractures associated with CSF leakage are treated expectantly and if the leak persists for more than a week dural repair is performed.

Depressed fractures lateral to the sinuses are usually managed by the neurosurgical team by elevation and if necessary repair of any underlying dural or cerebral damage; however, if the orbital rim and roof is involved, a combined craniofacial approach is often used to reposition the orbital margins and graft the roof.

Penetrating injuries are likely to be associated with contamination along the wound track and consideration must be given to opening the wound track and removing foreign material. Remember that wood is often best visualized by a MRI scan. A frontal craniotomy is performed and if the wound is orbitocranial, the frontal crown can be removed for greater access and replaced. Where there is dural repair under an orbital roof defect, a bone graft will add additional security.

Central depressed fractures of the frontal region may be associated with naso-orbito-ethmoid fractures that extend to the floor of the anterior cranial fossa, hence often complicated by CSF rhinorrhoea. A combined neurosurgical/craniofacial approach is needed to deal with this situation. The anterior fossa is explored and the fistula repaired intradurally and the naso-orbito-ethmoid fractures are repaired in sequence from posteriorly to anteriorly with grafts, fixation plates and canthopexies (Figure 36.11).

Figure 36.6 Bone can be taken from the inner table of the craniotomy bone flap if the skull is thick enough.

Figure 36.7 CT scan showing fractures of the anterior and posterior walls of the frontal sinus.

Figure 36.8 When there is a compound comminuted depression of the frontal bone involving both tables of the sinus and tearing dura and/or brain, the coronal flap exposes the area, the depressed fragments are removed, the area is gently cleansed, the dura repaired, the posterior sinus wall removed, the sinus ostia blocked and the frontal bone reconstructed with microplates or fine wires.

(b) The flap is attached to the dura and coats the floor and walls of the anterior fossa; it is seen here 'posted' between the frontal bone flap and the reconstructed frontal crown.

Figure 36.11 A completed frontal reconstruction after a severe frontal crush.

Naso-orbito-ethmoid fractures

These fractures occur as a result of direct trauma to the mid-face and, although they can occur in isolation, are frequently associated with other craniofacial fractures. Management is challenging because of the intricate and complex skeletal anatomy in close juxtaposition with the canthal ligaments, the nasolacrimal apparatus and the cribriform plate and brain above. Exposure, reduction and maintaining fixation have always been and still remain difficult.

Classification

These fractures may be unilateral or bilateral, simple or comminuted, closed or compound; they may occur in isolation or in association with more extensive damage to the craniofacial skeleton.

Multiple classifications have been proposed, Markowitz *et al.*¹¹ proposed Types I–III with increasing measure of complexity in each group. Gruss¹² attempts to relate to the fractures in adjacent bones. The problem with classifications in this area is the complexity and the difficulty of finding a language that reflects the

reality of each clinical situation.¹³ The author's view is that the closest method that is useful for measurement and comparison is one of alphanumeric scoring which quantifies the extent and pattern of bony damage in a global fashion.¹⁴

Principles of treatment

Historically, these fractures were treated by closed reduction and external splintage; the results were not only poor but rendered the secondary corrective surgery very difficult. Credit must be given to Mustardé,¹⁵ Dingman and Natvig¹⁶ and Stranc¹⁷ for identifying the need for open reduction and internal fixation, at the time, with wire. However restricted access and limited radiological assistance with diagnosis meant that the results remained suboptimal.

The modern approach is much aided by CT scanning, involves wide exposure using the coronal approach, accurate anatomical reduction becomes possible and fixation with micro- and mini-plates and screws ensures stability. In addition, primary bone grafting to delicate medial walls and graft support for the depressed comminuted nasal pyramid has vastly improved patient outcomes (Figure 36.12).¹⁸

Figure 36.12 CT fracture.

Operative management

The coronal scalp flap extended to the supra orbital margin then subperiosteally into the orbit will give tension-free exposure of the medial orbital walls, nasal bones and frontal processes of the maxillae as well as the orbitofrontal region. Care must be taken to preserve whatever bony attachment there is of the medial canthal ligament.

Transconjunctival incisions or subciliary lower eyelid incisions are used to expose the inferomedial orbital wall and orbital floor. An upper buccal sulcus incision exposes the nasomaxillary buttress and the margins of the pyriform aperture. In the case of compound fractures, local lacerations may be useful for access.

When the naso-orbito-ethmoid complex is fractured and displaced en bloc the fragments can be reduced and controlled by plate and screw fixation to the adjacent stable skeleton. In these cases the canthal attachments in continuity with the major bony fragment and its correct position is restored. In the more severe comminuted cases it is necessary to determine if the canthal ligament is attached to a fragment of bone. If this is so, this attachment is preserved and may be used to maintain the correct intercanthal distance. Transnasal wiring of the canthi is achieved by placing the wires posterior and superior to the lacrimal fossa. The wires are tightened; if there is much loss of bone the wire that is attached to the ligament can be passed through a small bone graft on one or both sides. Reconstruction of the medial walls is usually necessary; the author prefers thinned out inner table of ilium for this purpose. It is important to remember to reconstruct this area before tightening the intercanthal wires thus denying you access! The repair proceeds from back to front (Figure 36.13).

(a)

(b)

Figure 36.13 (a, b) A panfacial fracture where the naso-orbito-ethmoid complex has been repaired from posterior to anterior: the medial orbital walls grafted, the nasomaxillary processes plated, hence restoring the canthal ligaments, and a cantilever bone graft to the dorsum of nose to support the integument against collapse and contracture.

Figure 36.14 This shows the load-bearing direction of the buttresses, and on the right how plates are positioned on these lines.

In the comminuted cases, use of a costochondral graft fixed as a cantilever restores the nasal bridge projection and maintains the soft tissue expansion, which aids and minimizes secondary reconstruction, which is so often necessary in this condition.

With respect to the nasal septum, primary open reduction is not attempted beyond centralization by closed manipulation.

The management of the associated frontal sinus and cranial fractures are repaired at the same time. This implies a team working in harmony. It is the author's experience that a written preoperative plan setting out the sequence of events from beginning to end of the procedure facilitates harmony.

Management of nasolacrimal injuries does not usually involve early exploration, except where there is an obvious lacrimal system transection in an external laceration. Repairing this over a silicone tube is the preferred option. Despite its intimate proximity to the fractures, the nasolacrimal system is not often damaged, even with severe injuries.¹⁹ When late obstruction does occur, it is usually in the bony nasolacrimal canal. The more accurate the initial reduction, the less need for later dacryocystorhinostomy²⁰ (Figure 36.14).

Zygomatico-maxillary fractures

The face is generally described as having an upper, middle and lower third. The middle third is formed mostly by the maxillae, zygomatic bones and the nasoseptal complex. This section deals

with fractures of the zygoma and maxilla. As these bones articulate with each other, form part of the orbit, and the tooth-bearing maxillae form the upper jaw which articulates with the base of skull and occludes with the mandible, fractures of this complex may not be simple. Trauma to the middle third of the face has the potential for severe functional, psychosocial and aesthetic consequences. Whereas fractures of the mandible remain the most common form of single facial fracture, the zygoma is the commonest when multiple facial fractures occur. The ratio of males to females remains high, 3–4:1.^{2,21}

Anatomy

The zygoma and maxillae are part of the face between the lower jaw and the base of skull that together with the nasoethmoid complex compose the majority of the bones generally described as the middle third. It is important to understand the blood and nerve supply to the maxilla and upper dental arch. This assists with planning, safe incisions and for understanding the patterns of numbness of the skin and palate associated with maxillary fractures. The greater palatine canal transmits the greater palatine artery and nerve which supplies all of the bone and mucosa of the hard palate. Branches of the maxillary artery and maxillary nerve pass into the posterior maxilla through small foramina to become the posterior superior alveolar artery and nerve. This nerve supplies the molar teeth with a dental plexus. Branches from the infraorbital artery and nerve enter the anterior maxillary bone from the orbital floor and supply the anterior teeth. Fractures of the orbital floor and the anterior maxilla may result in numbness of the anterior teeth, whereas fractures extending low in the maxilla posterior to the first molar region may result in numbness of the posterior teeth. It is important to know that the maxilla gains blood supply from the gingival attachments to the alveolar bone and through its attachments to the soft palate from the pharyngeal palatine branches of the facial artery and the ascending pharyngeal branches of the external carotid artery. Both the trauma and the surgical exposure may significantly compromise the blood supply to fracture fragments.

There are strong horizontal elements in the maxillae, alveoli and hard palate which make up a foundation to support the three paired vertical bony condensations or buttresses (Figure 36.15).

The most anterior of these extends from the dentoalveolar arch in the region of the lateral incisor/canine region superiorly along the pyriform margin to the medial orbital rim and frontomaxillary suture. The middle buttress extends from the first molar tooth to the body of the zygoma and through this bone as the lateral orbital wall to the frontozygomatic suture. The posterior buttress is represented by the attachment of the maxillary tuberosity to the pterygoid plates and hence to the sphenoid bone.

The biomechanical stresses in the midface have been harder to assess than those in the mandible; however, the load paths for distribution of force appear to be the buttresses described above.²

Figure 36.15 This 3D image of the skull shows a fractured zygoma on the left and a normal bone on the right. The articulation with the sphenoid bone forms the lateral orbital wall, with the frontal bone at the fronto-zygomatic suture, with the temporal bone to form the zygomatic arch (visibly deformed in this image), with the maxilla in two places to form the inferior orbital rim and the zygomatico-maxillary buttress.

The zygoma makes a key contribution to the orbital contour, facial width and projection. Comprising as it does the inferolateral orbital rim, the zygoma articulates with the frontal bone superiorly, the maxilla inferiorly and medially and with both sphenoid and temporal bones posteriorly and laterally.

Four bony processes radiate from the zygomatic bone, providing strong articulations with the frontal, maxillary and temporal bones as well as the greater wing of the sphenoid bone. The bony junction between the temporal process of the zygoma and the zygomatic process of the temporal bone constitutes the zygomatic arch. The temporal fascia and masseter muscle are attached to the arch. These muscles are usually considered to be the major deforming force in maintaining displacement of a depressed zygomatic fracture. The superficial temporal vessels and frontal branch of the facial nerve lie immediately superficial to the arch. Deep to it pass the internal maxillary vessels, temporalis muscle and coronoid process. It is important to understand the value of maintaining the zygomatic arch when locating the zygoma appropriately in relation to the skull base in an antero-posterior, vertical and transverse dimension.²¹

Classification

In classifying occlusal fractures of the maxilla we seem to be stuck with Le Fort's original description. The Le Fort I pattern is a low horizontal fracture through the pyriform aperture and the zygomatic buttresses and pterygoid plate. The Le Fort II fracture has the upper detachment at a fracture line running across the nasal bones, through the inferior orbital rims and through the zygomatic buttresses and pterygoid plates. The Le Fort III pattern has the upper jaw detached from the base of skull at a

fracture line running through the nasofrontal suture, ethmoid bone, frontozygomatic suture and arches of the zygomas and the pterygoid plates.

The language associated with this form of description is now so embedded that it ceases to be scientifically meaningful; it does not take into account the degrees of comminution and displacement of fragments, nor does it mention the parasagittal fractures of the hard palate and the smaller dentoalveolar segment fractures of the upper jaw. It certainly does not relate the severity of the maxillary fracture to other areas of the craniofacial skeleton. It is the author's belief that alphanumeric classifications are superior in this respect.¹⁴

Classifications of zygomatic fractures, are many and varied.^{22–24} With the advent of CT scanning together with improved methods of operative exposure and fixation of the orbital zygomatic region, the extent rather than the pattern of fracturing was seen to be of greater significance. Gruss²² recognized the role of the zygomatic arch in accurate reduction and classified these injuries according to the level of bony damage to the zygomatic body and zygomatic arches. Cooter and David¹⁴ quantify the degree of bony comminution of each element of the zygoma as well as the level of displacement of the skeletal articulations.

Clinical assessment

With respect to fractures of the *maxilla*, the signs depend on the degree of displacement and comminution and indeed whether the fracture extends into the orbits and skull base and whether the zygoma's are involved as well. Intraoral examination may show the upper dental arch to be intact or it may be fragmented. There may be mobile dental alveolar segments as well. Malocclusion may be evident: the patient may notice it or it may be obvious on inspection. It is important to be mindful of pre-existing occlusal disharmony. In the typical fracture of the upper jaw with an intact alveolar arch, posterior and inferior displacement the occlusal surface will result in an open bite.

The external examination shows cheeks that are typically swollen, and there may be bleeding from the nose and bruising. There may also be emphysema from the air forced out of the paranasal sinuses. If the fracture extends into the orbit, swelling and bruising of the eyelids may be a dominant feature. A gloved figure on the hard palate exerting an upward and rocking force may elicit pain, crepitis and abnormal mobility. Diastases at the fracture sites may be felt at the nasofrontal and frontal zygomatic sutures.

When managing fractures of the zygoma, it is important to record the mechanism, direction and particularly the force of the impact, as this will assist in understanding the pattern of fracture. These observations may be very important in later medico-legal proceedings, particularly in cases of interpersonal violence. The association of zygomatic fractures with other

midface injuries, in particular fractures of the maxilla, has been noted above (see Figure 36.15).

The symptomatology typically relates to the effect of the displaced zygomatic bone on the surrounding soft tissues. The orbital soft tissues manifest swelling, ecchymosed and subconjunctival haemorrhages, particularly laterally. Double vision or blurred vision may be complained of due to orbital soft tissue swelling, ocular dystopia or primary ocular injury. Numbness or altered sensation in the distribution of the infraorbital nerve indicates a fracture in the region of the orbital rim. If the zygoma is medially displaced, trismus and complaints of malocclusion are noted when the arch fractures impinge on the underlying temporalis muscle. Patients sometimes complain of altered occlusion and in this situation occlusal disturbance by extension of the zygomatic fracture into the maxillary alveolar process must be excluded by careful intraoral examination.

Physical examination and especially palpation will readily identify displacement. Observation from above the patient provides an impression of loss of the zygomatic prominence.

The examining fingers are placed on the prominent part of the zygomatic body and will give a comparison with the non-injured side. When there is displacement of the inferior rim, there may be a palpable step at the infraorbital margin and this is usually painful. In isolated fractures of the zygomatic arch there may be a depression which is palpable. When the zygomatic fractures are part of extensive midface fracturing, for example in conjunction with maxillary fractures, the zygomatic arches bow outwards and the anteroposterior projection of the zygomatic prominence is diminished.

Intraoral examination shows bruising in the upper buccal sulcus. Alveolar extensions of the fracture or malocclusion caused by trismus or associated with midfacial and mandibular fractures can be noted at this time.

It is important to have a detailed ophthalmological examination similar to that necessary in isolated fractures of the orbital walls.

Imaging

Fractures of the middle third of the face were once investigated by plain radiology. This has almost completely disappeared and the most useful radiological investigation has become the CT scan with axial, coronal and three-dimensional reformatting. This is the standard radiological examination for fractures of the upper jaw and orbit and all but the most simple fractures of the zygoma.

Axial cuts show fractures of the posterior wall of the maxillary antrum and of the pterygoid plates. It is possible to identify midline fractures of the hard palate as well as dentoalveolar segmental fractures. Coronal CT scans of the midface give detailed information of the anterior maxilla and the relationships with nasoethmoid and orbitozygomatic fractures. When the fractures are primarily of the orbitozygomatic region, then the radiological analysis is similar to that described in the section on Orbital fractures.

Principles of management

The mainstay of surgical treatment for zygomatic fractures was for many years the Gillies technique of elevating by leverage from an incision in the hair-bearing scalp of the temple.²⁵ The Dingman variation¹⁶ or elevation from a lateral eyebrow incision is a more useful and elegant method as it also affords access to the lateral orbital wall and allows for frontozygomatic inter-fragment fixation.

An intraoral upper buccal sulcus approach gives access to the arch and body of the bone which can be elevated and fixation can be made at the zygomatico-maxillary buttress. Because of the pull of the masseter muscle, it became common practice, in order to prevent relapse, to add fixation using a wire at the frontozygomatic suture. It is now standard practice to employ miniplate fixation. Miniplate or microplate fixation together with wide operative exposure of the orbitozygomatic skeleton allows anatomical restoration of the zygomatic prominence with fewer positional disturbances of the globe, such as enophthalmos and vertical global dystopia.

Following clinical examination and CT confirmation of the fracture pattern, it becomes important to identify fracturing and comminution in and around the zygomatico-maxillary buttress and the inferior orbital rim, disruptions of the arch and at the zygomatico-frontal suture. Because of the deforming and displacing effects of the masseter muscle, the placement of adequate mini- or microplate fixation is necessary. The techniques of exposure, reduction and fixation are now well described. It becomes logical to subdivide fractures of the zygoma to those where there is no orbital wall involvement (the isolated zygomatic arch fracture) and the more common orbitozygomatic fracture and also those associated with other midfacial fractures, or the panfacial fracture.

Isolated zygomatic arch fractures

These result in the main from low-velocity injuries and the characteristic symptoms are those of trismus and a depression at the site of impact. This injury is usually best treated by the Gillies technique of closed reduction. A short oblique incision in the hair-bearing temple allows passage of an elevator deep to the temporalis fascia behind the depressed arch. This technique produces a stable reduction in majority of cases. If the arch fracture is not corrected, the cosmetic deformity remains and in extreme cases there is some long-term disturbance of jaw opening.

Orbitozygomatic fractures

An undisplaced fracture does not need operative intervention.¹⁶ Displaced orbitozygomatic fractures require careful open reduction and internal fixation on an individualized basis. Exposure via an eyebrow incision, a lower eyelid subciliary

skin muscle flap or transconjunctival incision reveals the zygomatico-frontal suture, lateral orbital wall inferior orbital rim, orbital floor and interior zygomatic arch. An upper buccal vestibular incision permits exposure of the zygomatico-maxillary articulation and anterior attachment of the masseter muscle to the zygoma. Following fracture mobilization and elevation, either by the intraoral approach or by using the elevator through the eyebrow approach, an anatomical restoration is achieved by visualizing the zygomatic articulations and checking the alignment of the zygoma with the greater wing of sphenoid. Miniplate fixation in the zygomatico-maxillary buttress is effective, however there may be comminution in this area and sometimes the bony attachments of the plate are thin. The zygomatico-frontal suture on its own is often not enough but it does provide the strongest bone for miniplate fixation. Two-site fixation will provide sufficient stability in the majority of fractures. When the orbital floor needs exploring then the orbital rim can be plated as well through the lower lid or transconjunctival incision.

Comminuted and grossly displaced orbitozygomatic fractures seldom occur in isolation and are almost always the result of high-velocity impacts producing major midface fractures involving the maxillae. In those cases, recognizing the disruption and restoring the arch is key to restoration of zygomatic projection and hence a very good marker for fixation of adjacent fractured bones.²⁶ In these cases a coronal scalp flap facilitates exposure, mobilization and reduction of the arch fractures.

Comminution and loss of bone at the major articulations, the anterior maxillary wall, the orbital floor and the lateral orbital wall demands careful operative exposure, reduction and reconstruction by primary bone grafting to avoid enophthalmos and orbito-ocular dystopia.

When dealing with *maxillary fractures*, it is important to have a preoperative dental assessment. Impressions of the dental arches and teeth can be used to cast a plaster model which is then cut through the site of the fractures. Restoration of the pre-morbid occlusion can be planned and an acrylic bite wafer constructed, which can be used intraoperatively and postoperatively to maintain correct occlusal relationships.

There is some discussion in the literature about the timing of definitive treatment of maxillary fractures. The desirability of performing surgical correction of midface fracture as early as possible after injuring has been championed by Gruss and Mackinnon²⁷ and Manson *et al.*,²⁸ their argument being that early accurate bony reconstruction will prevent the development of soft tissue contractures and hence post-traumatic deformity. It is the author's belief that there are other factors that must be considered when deciding on the correct timing of surgery. The foremost of these is consideration of the priorities of management of other injuries, such as associated brain injuries and other associated limb and intra-abdominal problems. It is also useful to have time to properly plan and assemble an operative team to be able to give the appropriate time and expertise to the restoration of the facial injury.²

Airway management may be compromised with other jaw fractures and great care needs to be taken when considering placement of endotracheal tubes at the time of surgery. Particular care should be taken with panfacial fractures, which may extend through the cranial base. Where there is massive craniofacial disruption with haemorrhage then there is a role for tracheotomy.

Fracture reduction by disimpaction used to be carried out using somewhat brutal forceps inserted with one prong in the nasal cavity, the other in the oral cavity so as to grip the palate bilaterally. It is possible to inflict further damage with this instrument. With the advent of wider exposure through coronal, buccal and conjunctival approaches, more delicate instrumentation can be used to diss-impact the fracture sites.

Stabilization of fractures is of course now achieved with miniplate fixation and when there is comminution and loss of bone at the buttresses, primary bone grafting is performed.

Once the impacted displaced maxilla has been reduced, the upper and lower jaws are stabilized in the pretraumatic occlusion using arch bars, the wafer and intermaxillary wiring. Where the zygomas are also fractured, these should be reduced as described above. They then provide a reference point for re-establishing the vertical buttresses.

In the case of an uncomplicated Le Fort I fracture, the vertical height can be determined easily by opposing the vertical buttresses at the pyriform margin and zygomatico-maxillary region, which can then be plated. Even when there are other fractures of the midface, at least one of the four anterior vertical midface buttresses will usually not be severely comminuted and so provide a guide for the correct vertical relationship. Once this has been established, miniplates are used to stabilize the reduced fracture using at least two screws on either side of the fracture. If there is loss of bone then bone grafting may be needed in one or more of these vertical buttresses. Once the vertical height has been established and stabilized, with or without bone graft, the maxillary fixation can be released, the surgical fields irrigated and the wounds closed. The jaw opening is controlled with light elastics and the wafer removed after several days when the patient is able to bite in the correct position (Figures 36.16, 36.17 and 36.18).

Management of complex midfacial fractures when the zygomas, maxillae and indeed nasal ethmoid fractures are involved (that is, fractures above the Le Fort I level) need different treatment sequences. The occlusal complex (i.e. mandible and maxilla) is stabilized and brought together in occlusion with the help of a preplanned occlusal wafer. The zygomatic orbital complexes are stabilized usually via a coronal scalp flap to give the forward projection offered by accurate reduction of the zygomatic arch. The occlusal complex can then be united with the orbital complex via the four vertical buttresses. Fixation of the buttresses can be with miniplates and/or bone grafting if necessary. Finally, the nasal ethmoid complex can be reconstructed by meticulous interfragmentary miniplate fixation and the nasoethmoid area as described earlier.

Figure 36.16 Maxillary fracture classification of Le Fort: The classical fracture lines – horizontal (I), pyramidal (II), total disjunction (III).

Figure 36.17 A typical Le Fort I fracture of the upper jaw – the fracture line is horizontal; there is an intact alveolar arch. The posterior and inferior displacement of the arch and palate result in the open bite seen clearly on this 3D image.

Complications

Zygoma

These include:

- deformity
- prominent plates
- disturbance of globe position
- ocular injury
- nerve injury.

Deformity was more common with older techniques of management where there was inadequate exposure and fixation. Soft tissue deformities, including sagging of the eyelid and cheek, after zygomatic dissections require meticulous repositioning of soft tissues (Figure 36.19–36.22).

Prominent plates are a common complication which may require plate removal on a subsequent occasion.

Disturbance of globe position in both the anteroposterior and vertical dimensions remains a major long-term complication. Enophthalmus and vertical globe dystopia are cosmetically and functionally disturbing. They are very hard to correct and in some cases may require osteotomies of the orbit to reposition part or the entire orbital box.

With regard to ocular injury, direct globe injuries are common in association with these fractures. The fracture of the lateral wall of the zygoma that produces the ‘cigar cutter technique’ can injure the optic nerve. Ophthalmological investigation will determine whether or not there are any retinal injuries as a result of the trauma.

Nerve injuries most commonly involved are those of the infraorbital nerve, causing persistent numbness, paraesthesia or

Figure 36.18 A patient with fractures at all three Le Fort levels. (a) Swollen, bruised, nasal and oral packing to control haemorrhage, and intubated to protect her airway. (b) The coronal CT slice shows the endotracheal tube, the oral packing and the fractures. (c) After 7 days, extubated, lacerations sutured, swelling abating, clinically there is right enophthalmos, flattening of the cheeks, flattening and widening of the nasoethmoid region and an anterior open bite.

Figure 36.19 Flattened right zygoma, the arch is bowed out, and the palpebral fissure is narrowed due to the enophthalmos.

hyperaesthesia in the distribution of this nerve. Most patients experience significant recovery of function early but occasional patients experience progressive improvement over a longer period of time, up to 18 months or more. A very small number go on to have disaesthesia, which can be distressing.

The maxillae

These include:

- malunion and malocclusion
- non-union
- facial deformity
- infection
- nasal obstruction
- lacrimal obstruction.

Figure 36.20 Depression of the zygoma which is both visible and palpable.

Malunion with associated malocclusion and loss of normal facial form are most significant complications of upper jaw fractures, particularly where there has been severe comminution in and around the midfacial buttresses. Deformity may require early intervention if there has been some relapse; however, long-term assessment leading to osteotomies and onlay bone grafts may be the answer in complex cases.

Figure 36.21 (a, b) Open reduction and internal fixation of a fracture of the left zygoma. Access was gained via a buccal sulcus incision, an eyebrow incision and a transconjunctival incision. Plates are seen at the frontozygomatic suture, the inferior orbital rim and the zygomatico-maxillary buttress. The orbital floor has been reconstructed with iliac bone.

Figure 36.22 Right zygomatic arch fracture exposed via a coronal scalp flap.

Facial deformity can also result from an alteration to the facial contour, for example where the anterior wall of the maxilla has been fragmented and there is scarring between the maxillary fragment and the overlying integument. The wide dissection necessary to secure adequate reduction is itself a cause of scarring at the periosteal level, which produces an ageing effect.

Infection tends to occur in and around plates and screws but in the long term, patients can come back possibly many years later with sinusitis resulting from obstruction to the sinus drainage or indeed screws that have eroded into the sinus cavities.

Nasal obstructive symptoms may follow upper jaw fractures through fracture dislocations of the nasal central cartilage bone. Correction is usually performed once the mucosa has soundly healed, at which time a septorhinoplasty may be performed.

Lacrimal obstruction is common in those fractures that involve the nasal ethmoid complex (Figures 36.23, 36.24, 36.25, 36.26, 36.27, 36.28 and 36.29).

Figure 36.23 The forward projection of the zygoma is assured by accurate reduction and plating of the zygomatic arch. Access is via the coronal flap and the fronto-zygomatic diastasis has been reduced and plated.

Orbital fractures

Because the orbit is situated between the cranium above and the midface below, it is frequently involved in the other fractures described in this chapter, that is the zygoma and midface, the naso-orbito-ethmoid, frontal and orbito-zygomatic fractures. Advances in imaging have led to a greater understanding of the anatomy of fractures; this in turn has led to more meaningful correlation between observed pathology and symptoms. A good example of this is the ability to image the medial orbital wall and understand the relationship between these fractures and persisting enophthalmos when they go uncorrected (Figure 36.30).²

Advances in imaging permit preoperative planning; the possibility of wide exposure enables reconstruction of both skeletal

Figure 36.24 Row's dissipation forceps can cause further damage to already compromised tissue.

and soft tissues; techniques of grafting and rigid fixation give rise to a high level of predictable skeletal anatomical restoration. The team approach is vital in managing orbital injuries; especially important is the relationship between the craniofacial surgeon and the ophthalmologist.

Anatomy

The orbit is composed of seven bones and shaped like a quadrilateral pyramid; it has a strong anterior rim and four thin walls that converge on a strong bony apex (Figure 36.31). The thick protective outer rim is formed by the frontal, zygomatic and maxillary bones. At the rim the orbit is ovoid in coronal section, becoming more rectangular towards the apex which is almost triangular. The roof, medial, lateral, and inferior (floor) are thin and respond to trauma each in their own way. The portion of the orbit in front of the transverse axis of the globe has little effect on the orbital volume, and hence the projection of the globe of the eye, but more influence on its vertical and transverse position. Alterations to the size and shape of the part of the orbit behind the axis of the globe determine the meaningful skeletal volume and therefore influence the projection of the globe.

Lang, citing Oehmann,²⁹ gives the mean lengths of the adult orbit as: roof: 50.5 mm, floor: 48.4 mm, lateral wall: 47.2 mm, medial wall 40.5 mm.

The eye is protected from blunt trauma by the orbital rim, this being least effective in the inferolateral area. The optic canal enters the orbit at the apex of the pyramid. The canal is on average 9.8 mm long and 4.6 mm wide at its narrowest point. The optic nerve may be injured within the canal, either by forces transmitted through the intact bony canal or the orbital contents, or when a fracture enters the canal. The nerve is further protected from impact by the orbital fat and from stretching by its tortuosity.

Surgical pathology and pathogenesis

Disruption of the orbit may result from fracture of the orbital rim and walls by extension of extrinsic fractures, that is those arising external to the orbit which are classified according to their major anatomical component (Table 36.1). Intrinsic fractures arise from indirect forces transmitted via the globe and periorbital soft tissues, which produce blow-out fractures of the orbital floor and medial orbital wall (Figure 36.32).

The *orbital roof* is formed by the frontal bone which is thick at the rim and the roof is arched in both the anteroposterior and transverse dimensions. It is relatively resistant to fracturing. Inferior displacement of the roof is the most frequent fracture in this area and in most cases is associated with disruption of the orbital rim. Roof fractures resulting from high-impact injuries to the frontal bone and extensions into the face are more frequently seen in children (Figure 36.33).

Figure 36.28 Old orbital trauma requiring a box osteotomy to correct the vertical dystopia.

The *orbital floor* is the site of the classic 'blow-out' fracture. The anterior part of the orbital floor medial to the infraorbital nerve canal is concave from front to back, posterior to the axis of the globe it becomes convex upwards because the maxillary antrum bulges superiorly and obliterates the angle between the floor and the medial wall. When reconstructing the floor it is important to restore this posterior convexity in order to prevent enophthalmos (Figure 36.34).

The *medial walls* are almost vertical and have a slight three-dimensional wave formation. The lacrimal bone and the lamina papyracea of the ethmoid bone form the thin, vulnerable portion of the medial wall that is subject to 'blow-out' and 'blow-in' fractures. Isolated medial wall defects in the middle and posterior third of the orbit increase the orbital volume and may cause enophthalmos. Until the advent of CT scanning these injuries were difficult to diagnose and often went undetected. The lacrimal drainage system lies at the anterior aspect of the medial orbital wall and is intimately associated with the medial

canthal ligament. Injuries of these structures are most frequently seen with naso-orbito-ethmoid fractures (Figure 36.35).

The *lateral orbital wall* is formed by the greater wing of sphenoid and the orbital process of the zygoma, it lies entirely posterior to the transverse axis of the globe. Isolated fractures are rare; fracturing usually being part of a zygomatic injury (Figure 36.36).

The *orbital apex* is formed by thicker bone which surrounds the inferior and superior orbital fissures and the optic foramen.

The extraocular muscles are separated from the bony walls of the orbit in its anterior half by fat pads. In the posterior orbit they are close to the bony walls and more vulnerable to trauma from fracture of orbital dissection.

Fractures of the orbit may be classified as being intrinsic to the orbital walls and those fractures of the walls that are associated with fractures of the bones that form the orbital rim. Intrinsic fractures of the orbital walls are characterized as blow-out or blow-in fractures. When there is extension of the fracture

to involve the orbital rim these fractures are often referred to as 'impure'!

The application of sudden blunt trauma to the periorbital soft tissues is transmitted as a hydraulic pressure wave to the orbital walls resulting in the fracture.³⁰ The orbital floor medial to the infraorbital nerve is thin and unsupported and breaks easily, as does the fragile lateral plate of the ethmoid bone. The sequelae of this disturbance include enophthalmos from the expanded volume of the orbital box combined with prolapse of orbital

contents into the adjacent sinus, possible muscle involvement in the fracture, damage to the infraorbital nerve and diplopia. These fractures usually result from a low-energy impact (e.g. a champagne cork in the eye!). The blow-in fracture³¹ is characterized by inward displacement of bony fragments of the walls and/or margins which results in decreased orbital volume and proptosis (Figure 36.37).

Low-velocity impacts from assaults or falls tend to produce simple linear or blow-out types of fracture involving one or two orbital walls. Medium-velocity injuries have a similar pattern of wall disruption but may be associated with disruption of the orbital rim. The orbital fractures that extend to the orbit from fractures of adjacent bones invariably result from medium- to high-velocity impacts.

The multiple wall fractures resulting from high-velocity impacts that are part of a panfacial fracture exhibit less well-defined patterns and have more comminution and bone loss.

Clinical assessment

Ophthalmological examination is an essential part of the clinical assessment of a patient with orbital trauma, the ophthalmologist being an essential member of the craniofacial team. In addition to the routine examination for fractures such as those of the zygoma, the orbital contents need to be examined by evert the lids with appropriate retractors lest globe destruction be missed. Visual disturbance must be investigated further. The clinician must test for altered sensation in the distribution of the nerves passing through the orbit. Enophthalmos is difficult to determine in the presence of swelling but becomes obvious as the swelling abates. Early marked exophthalmos is indicative of reduction of the orbital volume and requires urgent ophthalmological and radiological examination to determine if there is impingement of bone on the orbital contents or damage at the orbital apex. It is important to test ocular motility. In children, the rare event of a small fracture pinching and entrapping the

Figure 36.38 The cause of the restriction of upward gaze can be seen in the coronal CT scan: the belly of the inferior rectus muscle is pinched in a small orbital floor fracture. Early release is indicated.

inferior rectus muscle can occur. To avoid damage to the muscle early intervention is recommended. These patients are often very distressed by attempted eye movements (Figure 36.38).

Imaging

CT examination is the diagnostic investigation of choice in orbital trauma, this form of imaging is mandatory for accurate diagnosis and when planning surgical reconstruction.

High-resolution axial CT examination with films of both bone and soft tissue windows show damage to the medial and lateral walls and extensions of fractures beyond the orbit into the adjacent bones. Direct coronal views show the orbital roof, medial orbital wall and orbital floor. When a pure blow-out fracture is suspected, direct coronal scans of the orbit will identify both the extent of the floor and the medial wall involvement and the nature of the soft tissue abnormality. Modern programmes have the tools to define and measure the area of bone destroyed and give a guide to the amount of reconstructive material that may be used at operation. Careful studies will identify the prolapsed fat and the relationship of the orbital muscles to the fracture. Submucosal haematomas or mucosal polyps of the maxillary sinus can be differentiated from herniated soft tissues. Sagittal images viewed in the line of the inferior rectus muscle will show the relationship to the bony damage and also demonstrate the nerves as they pass through the orbital floor.

Comparison with the contralateral orbit provides a qualitative assessment of the degree of enophthalmos. Postoperative CT scanning reveals the results of surgery (Figure 36.39).

Management

As always with craniofacial trauma, the management of orbital fractures is multidisciplinary, the craniofacial surgeon relying heavily on the relationship with the ophthalmologist. Minor

disruptions which do not exhibit clinical signs or cause symptoms are managed conservatively, but followed for some weeks to ensure that late problems such as developing enophthalmos do not occur.

The aim of surgical treatment is accurate restoration of the orbital rim, followed by reconstruction of the orbital walls. The orbital rim is reduced and fixed with miniplates or microplates. The orbital walls are usually reconstructed with bone graft (the author's preference) or alloplastic material. It is important to perform the operative repair as early as possible to minimize the development of soft tissue fibrotic changes. Early swelling and insufficient multidisciplinary work-up usually prevent immediate intervention, however there are exceptional circumstances such as bony fragments impinging on the globe or optic nerve as can occur in some lateral wall fractures and 'blow-in' fractures.

Surgical exposures to the orbit are described elsewhere. The coronal scalp flap giving the widest access to the medial wall in its middle and posterior third. It also gives good access to the lateral orbital wall, roof and, in the experienced craniofacial surgeon's hands, the orbital floor.

The latter can be approached via a subconjunctival route with or without lateral canthotomy, a subciliary approach, or via a lower lid crease incision. More recently there have been advocates of a medial wall repair via a transcaruncular approach to the medial orbital wall (Figures 36.40 and 36.41).^{32,33}

Proper reconstruction of the orbital 'box' returns the globe to its pre-injury position with full maintenance of ocular mobility. Subperiosteal dissection of the orbital walls delineates the fracture and dissection continues so as to expose the surrounding stable bony margins. The herniated soft tissue must be retrieved from the defect in order to restore intraorbital volume and prevent fibrosis.

If the blow-out fracture of the orbital floor is small and isolated, it may be possible to elevate and manipulate the fragment to override the solid margins of the defect. For most defects this

Figure 36.39 Before and after coronal CT showing the repair of a severe blow-out fracture of the orbital floor with a bone graft taken from the blade of the ilium.

Figure 36.40 A sagittal illustration of the transconjunctival approach to the orbital floor. The approach to the orbital floor begins inferior to the tarsal plate of the lower eyelid. The incision is made in front of the orbital septum down to the maxilla just inferior to the orbital rim. The periosteum is then elevated over the rim to expose the floor.

is inadequate, and the introduction of an orbital wall graft is required.

The choice of materials for orbital wall reconstruction lies between autogenous bone or cartilage and various forms of alloplastic implants. Historically there are many materials used; at one time silastic sheeting was popular, but its tendency to extrude has led to other materials being preferred. Titanium mesh is well tolerated, but with the ingrowth of fibrous tissue it makes reoperation difficult and it is hard to remove. Porous polyethylene (MEDPORE) has become popular for reconstruction. It does not show on postoperative radiology. The author believes that autogenous bone remains the best material for orbital repair. It has minimal tendency to extrude or become infected and it readily remoulds and shapes to the normal orbital contour. The disadvantage is donor site morbidity, which becomes minimal with operator experience.

Calvarial bone enjoyed widespread popularity and is best used when a craniotomy is part of the treatment regimen, and it can be harvested from the inner table of the calvarial bone flap. Splitting off a layer of the outer table risks damage to the brain or at least an unsightly contour defect of the skull. The bone thus harvested is often rigid and difficult to shape.

Split rib graft is available in large quantities; however the author's preferred option is the smooth inner surface of the blade of the ileum approached via an iliac crest incision which can be minimal in length. The quantity and quality of the bone is most suitable for the task of orbital wall reconstruction (Figure 36.42).

(a)

(b)

Figure 36.42 Bone harvested from the inner side of the ileum is smooth, and can be easily contoured for orbital reconstruction.

In uncomplicated blow-out fractures, after anatomical restoration of the orbital bony anatomy with or without a graft, the orbital soft tissues are allowed to redrape.

A forced duction test is performed by grasping the rectus muscle insertions with forceps and moving the globe to demonstrate that muscle entrapment has been relieved. The lid and conjunctival incisions can be closed in a single layer.

In the case of a very extensive defect when the posterior margins may be difficult to reach and define, Tessier suggested removal of the orbital rim, placing microplates on the fragment,

thus obtaining a much better exposure. Once the repair is completed the plated rim is replaced (Figure 36.43).

Complications

Complications of orbital fractures are still seen in spite of the use of modern treatment modalities. Residual problems may stem from the initial injurious process, from incomplete surgical restoration, or from the operative exposure itself.³⁴

Figure 36.43 (a, b) Patient with a massive orbital floor fracture and global dystopia. (c, d) Removal of a segment of orbital rim exposes the orbital floor which is reconstructed with bone graft. (e) The rim replaced and fixed with microplates (after Tessier). (f) Postoperative correction. Source: Winn HR. *Youmans Neurological Surgery*, 2011. Reproduced with permission of Elsevier.

Ocular problems usually relate to the initial injury and are not affected by the bony reconstruction. Persistent diplopia in the initial postoperative period is not uncommon but is seldom noted in long-term follow-up. Careful ophthalmological assessment will detect any muscle weakness or restriction of gaze and some of these patients may need ocular muscle surgery.

With significant bony displacement at the orbital apex and superior orbital fissure, optic nerve damage and/or ophthalmoplegia can occur.

Enophthalmos is the commonest complication; this has become less since the recognition of and the ability to treat medial wall fractures. It remains hard for the treating surgeon to judge the volume of orbital contents lost or damaged by the trauma and hence if and by how much to overcorrect the orbital wall defect.

Global dystopia may occur with poorly reduced fractures of the bones constituting the orbit, as well as under- or overcorrection of the walls. In a very few cases this may need secondary orbital osteotomy to correct the deformity.

Canthal dystopia occurs medially when the ligament has been disrupted and not correctly reattached, and laterally, most commonly when a lateral canthotomy has been performed and inaccurately repaired.^{35,36}

Mandible fractures

Fractures of the mandible are common, in a recent report from a major Australian trauma centre these fractures were the most common requiring surgery, although orbital fractures, many of

which did not require surgery, were the most common in the series.³⁷ The incidence of mandibular fracture is higher in males than in females with a peak incidence in the third decade of life. Interpersonal violence accounts for the majority of fractures in males, whereas falls account for the majority of fractures in females.³⁸ With the ageing population in Western society, the incidence of mandibular fractures in the elderly resulting from falls is increasing.

The mandible is a very strong bone, designed to withstand forces applied in mastication, however it has areas of weakness that include the condylar processes, the angle and the anterior body in relation to the deep root of the canine tooth. The fact that it has an articulation with the base of the skull at the temporomandibular joint complicates the management of fractures of the mandible. The joint's integrity needs to be restored and its position and function respected in the management of fractures of this bone.

Anatomy

This robust bone occupies a prominent exposed position in the facial skeleton. It articulates with the cranial base through its condyles which lie in the glenoid fossae. The joint is divided into two cavities by a disc of fibrocartilage. The joint acts as a hinge but also allows a sliding movement in the anteroposterior plane.

The mandible comprises a number of components: the condyles, the coronoid processes, the rami, the angles and the two halves of the body joined arterially at the symphysis. Viewed from the lateral aspect, the ramus forms an angle of about 120° with the body of the bone in the adult, slightly more than the very young and elderly. When viewed from the superior aspect there is a slight divergence of the rami. The alveolar portion of the bone supporting the molar teeth does not follow the same line as that formed by the lower border of the mandible.

Functionally, the mandible can be regarded as two conjoined L-shaped cantilevers, acting under the influence of the masticatory muscles. The temporalis muscle inserts predominantly into the medial surface of the coronoid processes, the masseter into the lateral surface of the angle of the ramus. The medial pterygoid muscle inserts on the medial surface of the angle and lower ramus, together with the masseter, it forms a powerful sling acting on the ramus. The two heads of the lateral pterygoid muscles unite to insert into the anterior part of the capsule of the temporomandibular joint and the pterygoid plate. The action of this muscle is important in functional recovery after intracapsule fractures of the condyle and its insertion must be preserved.

In cross-section, the body of the mandible is seen as being composed of a strong inner and outer cortical plates of bone between which are inserted the teeth and their roots which are imbedded in cancellous bone. Between the two plates of cortical bone runs the inferior dental canal which contains the inferior dental nerve, entering the bone at the mandibular foramen and exiting at the mental foramen.

Classifications

Mandibular fractures may be classified simply on the anatomical site of the fracture (Figure 36.44). They may be linear or comminuted, and the fragment size may be displaced or undisplaced. The distinction between compound and non-compound mandibular fractures is important, as any displaced fracture through a tooth root is inevitably compound and fractures of the ramus and condylar region are not compound unless caused by an entering agent, such as a gunshot. The presence or absence of teeth on either side of the fracture line is also important from the viewpoint of treatment by intermaxillary fixation or interfragment fixation, and this justifies the classification (Figure 36.45).³⁹

- Class I – teeth on either side of the fracture
- Class II – teeth on the one side only
- Class III – edentulous.

Clinical assessment

The clinical assessment is based on a thorough history and complete examination, the history being very important because many cases of fractured mandible are due to assault and vehicle accidents which may involve subsequent litigation. The history should establish whether dentures were worn at the time of the accident and whether there had been any previous disease. The fractured mandible may be a part of multiple traumas and resuscitation is the first priority; never the less it is important even in cases with life-threatening injuries to make a thorough preliminary assessment by palpation of the facial skeleton and examination of the oral cavity including the dentition.

Where possible, get the patient to point out the areas of pain or tenderness and ask the patient to feel the teeth with the tongue tip to detect dental irregularities, chipping and loss of dental restoration. The patient is asked to map out any areas of numbness on the face and an accurate record of bruising is made.

Figure 36.44 Common fracture sites of the mandible. The commonly used descriptive terms for the anatomy of the mandible.

(a)

(b)

Figure 36.45 (a) A parasymphiseal fracture with teeth on both fragments: Class I. A left angle fracture with a tooth on one fragment: Class II. (b) Fractures in an edentulous mandible: Class III.

External and internal lacerations may give a clue to the mechanism of fracture and external chin lacerations may point to a condylar fracture. Steps in the dental arch are noted as they indicate a fracture, as may local swelling and bruising of the gingival tissues or lacerations of the oral mucosa. When the patient is asked to bite the teeth together, they can determine whether the occlusion feels normal and the nature of the occlusion is noted. If the patient is edentulous, the dentures are inspected for signs of injury.

The assessor then proceeds to palpate the mandible through the overlying soft tissues from behind and from in front and notes tenderness and deformity. Compression of the angles will usually cause pain in an otherwise occult fracture. Examination of the temporomandibular joint for pain, swelling, loss of mobility and abnormal movement or crepitus is important.¹⁰

Neurological examination may show sensory loss in the lower lip from damage to the inferior dental nerve.

Imaging

Radiological assessment classically involved the OPG and the Towne's anteroposterior view. The OPG allowed inspection of the entire mandible and mandibular dentition on a single film,

being a composite of the two lateral views. However, the tomographic process results in blurring in the symphyseal region and fractures here may be missed. Moreover, the patient needs to sit and this may be impossible in severely injured or uncooperative patients. This technique remains the mainstay of assessment and follow-up radiology for mandibular fractures. CT images give the most useful information on the integrity of the buccal and lingual plates and modern CT scanning can also give good views of the temporomandibular joints when they are involved in the fracture pathology (Figure 36.46).

Early management

Patients with compound mandibular fractures need to be admitted to hospital, treated with intravenous antibiotics, given appropriate pain management and prescribed an adequate fluid intake and instructed in maintain oral hygiene. In dentate patients with a displaced fracture, dental impressions are taken to provide a plaster cast of the occlusion in the position resulting from injury; these casts are then cut at the fracture site and mounted on an articulator in a predicted pretraumatic position so that they can be used as models in planning how to restore

Figure 36.46 An orthopantomogram showing a fracture of the right angle of mandible involving the partially erupted wisdom tooth. Note the clarity of the image laterally compared with the relative lack of definition at the symphysis.

the pretraumatic occlusion as accurately as possible. From this structure an acrylic wafer can be made for use in the surgical reduction and fixation of the fracture.

Timing of definitive treatment

Often the clinical priorities of other injuries have to be taken into account. Soft tissue lacerations should be debrided and sutured within 12 h of the injury. Some authorities favour early reduction and immobilization of compound fractures of the mandible.⁴⁰ Others⁴¹ believe that the best results occur if operations are done with good instrumentation with experienced staff after thorough assessment and work-up and this may extend the period of time between trauma and definitive treatment if an increased infection rate was not noticed under these circumstances.

Conservative management

Stable fractures without displacement are best treated conservatively by a liquid non-chewed diet and analgesics. Sometimes a soft padded neck collar may be worn to support the chin. This regime can be used for unilateral fractures of the angle and body of the mandible in elderly edentulous patients and in greenstick fractures of children. Some ramus fractures are splinted by the masseter muscle laterally and the medial pterygoid muscle medially and lend themselves to conservative management. Undisplaced hairline fractures of the body or angle which extend to a dental root may cause more of a problem with respect to affecting the viability of the tooth, so long-term dental follow-up is mandatory. In a sensible patient who is likely to comply with good follow-up and dental management, conservative treatment would have a good chance of success.

Principals of operative fixation

Historically, mandibular fractures were fixed by external intermaxillary fixation, but this method has faded into antiquity. More recently, closed reduction and intermaxillary fixation,

where the jaws were fixed together in occlusion for a prolonged period of time, has been used, aided in class II fractures by interfragmentary wiring. However, these methods are rarely practised today, or even thought of since the advent of internal osteosynthesis with miniplates. Although there is still much debate about the number, siting and composition of the plates, this mode of treatment is widely preferred and allows early release of intermaxillary fixation, followed by support of the mandible with light elastics which entails minimal time in hospital, ability to feed and facilitation of oral hygiene. It also avoids the risks associated with prolonged intermaxillary fixation and the presence of the devices that are used to secure it.⁴²

When a fracture extends into a dental root, it is arguable as to whether it is necessary to extract the tooth or not in order to lessen the risk of subsequent infection. The consequence of removing such teeth and converting a potentially stable fracture into an unstable fracture is less of an issue with miniplate fixation used as the primary treatment. The author's rational has been to retain teeth in the fracture line where these teeth have potential function, either in establishing the occlusion or as a fixation post for subsequent prosthodontic work, assuming that the teeth have a chance of survival. When there is severe fracturing of the tooth with comminution of the surrounding alveolar bone, infection is almost certain and the tooth should be extracted. When an impacted third molar is involved in an angle fracture it is customary to extract it as the tooth rarely has a function part in the occlusion, and retention of such a tooth may lead to future infection. Rubin *et al.*⁴³ have shown that completely erupted molars may be left in a fracture line without increasing risk of complications.

Miniplate osteosynthesis

Miniplate fixation in the modern context goes back to 1958 when the Association for Osteosynthesis/Association for the Study of Internal Fixation (AO/ASIF) system was introduced and showed the value of rigid mobilization and coaption of bone ends and securing bone union. Initially the plates were made of stainless steel before Hans Luhr developed a system in Würzburg

using vitallium and producing compression with bicortical screws. More recently, titanium plates have been preferred because they are malleable, radiolucent and have high biocompatibility. The search continues for suitable resorbable implants for mandibular fixation.⁴⁴

Success in plating fractures of the mandible depends on an understanding of the mechanical forces acting through the mandible during mastication. The mandible is normally subjected to tension forces of its upper border and to compression forces at the lower border unless the fracture is inherently self-stabilizing. There will therefore be distraction of the upper or alveoli end of the fracture and the plating system must counteract this distraction. Champy *et al.*⁴⁵ described an ideal line for the siting of the plate as shown in Figure 36.47.

They demonstrated the presence of rotational torsion forces in the anterior mandible, which is a three-dimensional structure upon which bilateral muscular groups act. They also recommended a lower border plate as well as an upper border plate to give better control of these torsional forces. In the tooth-bearing alveolar area the thickness of the bone is variable and unsuitable for screw fixation; the upper boarder of the mandible is therefore the ideal site. Champy *et al.* showed that the average thickness of the outer cortex of the mandible is 5 mm but in some areas the cortex is less than 3 mm thick. There is therefore some danger of injuring the inferior dental nerve. Care should therefore be taken to drill only through the outer cortex and use the smallest possible screws.

In certain situations the usual tension/compression relationships can be reversed. This may be the case when a bite load is placed just anterior to an angle fracture and the contralateral muscle sling is functioning normally but the ipsilateral sling is ineffective from post-traumatic oedema and bruising.⁴⁶ In addition to this theoretical concept of intermittent reversal of the normal tension–compression zones, there is also some clinical evidence of unfavourable results with angle fractures

treated with only a single plate as Champy suggests. Levey *et al.*⁴⁷ had a significantly higher complication rate with using one plate rather than two. It has been the author's experience that the Champy principle with a single upper border plate for angle fractures has been more than satisfactory. It has emerged, however, that in non-compliant patients firmer bracket fixation by applying a second plate may be needed.

The Champy technique of upper border single-plate osteosynthesis is mostly successful for angle fractures providing the patient is compliant and does not chew and the reduction is accurate.

Compression plates

Because the mandible is an asymmetrical structure, bicortical screws and compression plates are required. The compression plating systems have a consistent potential drawback. Because the compression is applied across the buccal plate of bone there is the possibility that the fracture line may be opened on the lingual side and this can lead to a significant cross bite. Efforts have been made to contour the plates extremely accurately so that this does not occur. In practice, it does not appear that the healing claimed by compression systems is any more advanced of that than non-compression systems.

Operative management according to Champy

The patient is prepared in the usual fashion using an acrylic wafer to register the occlusion and the application of arch bars or intermaxillary fixation screws. A naso-endotracheal tube is usually necessary. The incision to explore an angle fracture is placed just lateral to the anterior boarder of the ramus and runs

Figure 36.47 (a) The mandibular tension line is at the junction of the dentoalveolar bone and the mandibular base bone (Champy). (b) The anterior body reverse tension line. The anterior lower borderline is the site for lower border plates in conjunction with upper border plates when fractures cross this area (Champy).

down beyond the third molar just lateral to the inferior buccal sulcus. The incision is deep into the bone and the fracture line exposed by subperiosteal dissection down to the inferior border of the mandible. A posterior border retractor combined with a notched anterior border retractor will give good exposure. When the third molar is to be extracted, care is taken not to fracture the external oblique ridge of the bone as this is important for the fixation.

After removal of the tooth, the socket is cleaned and irrigated; care is taken not to injure the inferior dental nerve which is sometimes exposed by the fracture. It is important to spend some time cleaning the edges of the fracture of granulation tissue and irrigating the area thoroughly in order to wash away debris. The fracture is reduced manually into its correct anatomical position. The occlusion is established and intermaxillary fixation is applied. The pretraumatic position of the occlusion is established by the use of the dental wafer. Once the jaw is secured with the intermaxillary wiring and the fracture reduced anatomically, it is relatively easy to apply the miniplate

according to Champy's principles. A four-hole titanium miniplate with two monocortical 5 mm screws on either side of the fracture line is adequate (Figure 36.48).

The incision to explore a fracture of the body is placed to the labial side of the inferior sulcus. In order to preserve the mental nerve, the scalpel is angled back sharply under the sulcus down to the bone, the periosteum is incised and the fracture exposed by subperiosteal dissection in the usual manner. If the fracture is laterally placed, the mental nerve in its foramen must also be exposed and preserved. In both the angle and body fractures, care must be taken to drill only the outer cortex and the plates are bent as accurately as possible to conform to the contours of the mandible. Some plating systems use malleable titanium with no memory and these can be contoured very accurately with the screw pressure.

Sometimes it is warranted to modify the standard method in fractures in the angle area on the external oblique ridge, some operators preferring the six-hole plate and longer screws and where there is some doubt about the reduction of the fracture at the lower

(a)

(b)

Figure 36.48 A left angle and right body fracture in a jaw with carious teeth and teeth involved in both fractures. The monocortical plates have been used according to Champy after removal of the teeth in the fractures.

border of the mandible, some operators prefer to place the second plate in this region, still using an intraoral approach but combined with percutaneous drilling and screwing through a cannula.

With body fractures, it is usual to apply the four-hole plate to the upper border of the body with two monocortical screws on either side of the fracture line and a similar plate applied to the lower border, avoiding the nerve. Intraoral wounds are usually closed with an absorbable suture. The temporary intermaxillary fixation is removed and the excursions of the mandible are checked with special attention to the ability to bite into occlusion. The arch bars or fixation screws are left *in situ* and the jaws are supported by light elastic rubber traction to overcome any imbalance in the masticatory muscles caused by injury and swelling. The elastic traction may be maintained for a number of days, being removed once the patient settles into their normal occlusion.

The postoperative management includes a dose of intravenous antibiotics at the time of surgery, clear fluids, soft diet and mouth toilet. Postoperative radiology is important to check the reduction of the fracture. This regime facilitates early discharge from hospital and encourages self-care. Follow-up at regular intervals including a postoperative dental assessment is important and long-term follow-up is routine for 12 months. If there are clinical reasons, the patient may be seen beyond that in order to check the healing of scars, the recovery of any areas of sensory loss and the return of normal mastication.

Complications of fractures of the body and angle of the mandible

Complications include:

- infection
- non-union
- malocclusion and malunion
- plate exposure
- nerve injury and/or dental injury due to drilling the body of the mandible.

Infection

The instance varies in different reports and the causes are disputed. The argument that early surgery on the mandible prevents infection⁴⁰ has been made; others⁴⁷ reported a high incidence of infection when plates were used. Anderson and Alpert⁴⁸ gave special attention to fractures of the mandibular angle when only one miniplate was used without intermaxillary fixation, giving it an infection rate of 22%. Once infection is diagnosed and a wound culture is taken, intravenous antibiotics are started. If radiology reveals a fracture displacement or bone sequestrum or any complication relating to a plate, the fracture is explored and the foreign and necrotic material removed. Teeth in the fracture line need to be extracted. The occlusion can be re-established and where there is bone contact with the fracture, replating can be undertaken. If there is discontinuity of the bone, a bone graft may be inserted with rigid fixation and adequate drainage.

Non-union

This is clinically indistinguishable from infection and in principle the treatment is the same.

Malocclusion and malunion

Some malocclusion can result from inadequate or inappropriate reduction of the fracture but may also be a consequence of orthodontic movement of teeth which have been wired to arch bars or the result of imbalanced masticatory muscles and the management can be relatively conservative. If the cause of malocclusion is shown by X-ray to be due to inadequate reduction of the fracture, it may have been due to the operative procedure and reoperation is necessary to reduce the fracture again and fix it more strongly in its correct position. If there is true malunion and the bone is united and there is a malocclusion then an osteotomy will be required.

Plate exposure

Miniplate exposure may be due to poor operative technique and suturing mucosa or due to postoperative trauma. It is usually safe to leave the plate exposed until healing is complete in six weeks, in which case the plate can be removed without compromising the result.

Nerve injury

Injury to the inferior dental nerve is usually the result of the trauma but may occur with poor operative technique and radiology will show whether a screw is impinging on the inferior dental nerve canal. Sensory recover or failure of recover to the inferior dental nerve should be watched for over 12–18 months. Some operators would uncover the canal and attempt to anastomose the nerve or indeed graft it.^{49,50}

Fractures and fracture/dislocations of the condyle

Surgical pathology

The condyle is the part of the mandible that passes vertically up from the posterior border above the sigmoid notch to the glenoid fossa of the temporal bone. Fractures may occur at any level in the sigmoid notch, thereby including a variable amount of the ramus in the condylar fragment (Figure 36.49).

Sagittal fractures of the condylar head are rare; however, there may be dislocation of the fractured condyle in a posterior, anterior, medial or lateral position and very rarely vertical dislocation into the cranial fossa.

Attempts at classification

The classification devised by Lund⁵¹ has the merit of being very simple. Type I: enlocated head with or without displacement at the fracture site with no more than 60° angulation. Type II: a dislocated head with 90° or more angulations. Lund also described this fracture as either high, involving the head or neck, or low, at the base of the condylar process (Figure 36.50).

Figure 36.49 Anatomy of condylar fractures. A condylar fracture is one that separates the condylar head from the corpus of the mandible, but excludes the coronoid. These fractures all pass through the sigmoid notch and are deemed high or low.

Figure 36.50 Lund's classification of condylar fractures.

Clinical assessment

A proper clinical assessment commences with a thorough history as well as a complete examination, and a history of the causation of the fracture will often point in the direction of the

temporomandibular joint. Pain in the region, together with trismus, is a common combination in these circumstances. Attempting to open the mouth will be painful and the movement restricted and this may be bilateral. When the fracture is unilateral, any attempt at opening of the mouth will cause deviation of the chin point towards the affected side.

Bleeding from the external auditory canal may indicate a compound fracture into the external ear canal and otoscopic examination of the meatus may show a tear in the lining of the canal. Bimanual palpation of the condyles during movement may detect swelling, tenderness and the absence of a normal condylar head. With respect to occlusion, typically bilateral condylar fractures cause an anterior open bite not present before injury, whereas a unilateral fracture causes lateral cross bite. The clinician should always keep in mind the possible presence of multiple facial fractures.

Radiological assessment

The standard OPG and Towne's views have mostly now been replaced by CT scanning, and the modern fine-cut CT scan can be reproduced as a solid image and even converted to nylon models which may, in complicated cases, be of great help in surgical planning (Figure 36.51).

Principles of treatment

The management of these injuries is controversial. In children, there may be restitution of the fractured condylar head and remodelling of the displaced fracture and associated compensatory growth which would support a conservative plan of management in the young. This is not repeated, however, as growth nears completion.⁵² When the fractures are intracapsular and unable to be successfully reduced in an open fashion then the management is conservative, relying on reduction of pain, supporting the occlusion and early mobilization with the application of dental arch bars and elastic traction.

In the mature patient, when there is a fracture that can be fixed by open reduction and internal fixation with plates or other devices, this can be undertaken when the fragment is dislocated or when fixation of other fractures in the face require an intact mandible. Because the surgical approach to the temporomandibular joint is not an easy one and may be associated with complications such as facial nerve damage, there are several criteria that should be fulfilled for operative procedures to be acceptable:⁵³

- The operative procedure must provide full restoration of normal function and occlusion within 6–12 weeks.
- The fracture must be reduced so that the muscles which act on the condyle regain normal tension and position.
- The displaced fragment must be large enough to be reduced and stabilized in three dimensions.
- The stabilization must be able to be maintained until bone union occurs.
- The operation must not damage the attachments of the lateral pterygoid muscle for the condylar head.
- There must be no operative morbidity from injury to the nerves and other important structures or to mandibular growth.

Figure 36.51 (a) A 3D CT image of a patient injured in infancy, there is left temporomandibular joint ankylosis and a typical growth deformity. (b) A nylon model showing the pathology can be useful when planning reconstructive surgery.

Operative management

Zide and Kent⁵³ produced a list of absolute indications for open reduction and internal fixation of fractures of the condyle. Other authors have slight variation on this list but the principals are essentially the same:

- Fracture dislocation of the head into the middle cranial fossa or into the temporal fossa if associated with clinical disability
- Intra-articular foreign body
- Lateral extracapsular dislocation of the condyle
- Inability to open the mouth or to bring the mandible into occlusion after a week with evidence of bony block
- Compound injuries (e.g. gunshot wounds)
- Displaced condylar fracture where the fracture line is near the lower border of the sigmoid notch and the head is dislocated from the glenoid fossa
- Condylar fracture where the vertical displacements associated with displaced fractures of the upper jaw.

The ideal situation is where there is enough bone substance to hold two plates, giving rigid fixation and a capacity for immediate mobilization. The condyle may be approached through an intraoral incision and various skin incisions. Lately, some authors have used endoscopic assistance in this surgery. The author has found the most acceptable approach in his practice is through a coronal scalp flap, but extended in front of the ear to the level of the tragus. It is often unnecessary to make the full coronal incision. Once the zygomatic arch has been exposed, the masseter muscle is exposed and may be transected giving a very good exposure to the condyle, upper part of the mandible and hence the fragments (Figures 36.52 and 36.53).

Brown and Obeid⁵⁴ reviewed the methods of stabilization of the fracture when it has been exposed and reduced. Surgeons have used various types of interosseous wiring, Steinmann pins

with or without wiring and external fixators and miniplates; the latter have the great advantage of giving three-dimensional stabilization while allowing early return to normal function.

Complications of condylar fractures

These include:

- growth disturbance,
- avascular necrosis,
- ankylosis of the temporomandibular junction,
- malunion and other temporomandibular junction dysfunctions.

Growth disturbance

The problem is peculiar to childhood, of course, and may give rise to considerable facial asymmetry. Where the fracture is associated with infection, then severe growth disturbance may occur. This is often seen in developing countries where malnutrition may play a part (Figure 36.54).

Avascular necrosis

This can be seen when an intracapsular fracture detaches a fragment of the head of the condyle which is denuded of its bloody supply.⁵⁵ It may lead to pain and temporomandibular joint dysfunction. The avoidance of a vascular necrosis is assisted by maintaining all residual capsule attachments of the proximal fragment.

Ankylosis of the temporomandibular joint

This complication may develop when there has been tearing or disruption of the articular disc associated with comminution of the condylar articular surface as an intracapsular fracture. Its occurrence is minimized by early mobilization of the jaw and by careful follow-up. The patients at risk are those who have, for

Figure 36.52 External incisions for exposure of the condyle. The coronal flap 'relocates' the frontalis nerve: the act of turning down the flap relocates the nerve to a level below the sigmoid notch.

other reasons, long period of intermaxillary fixation or where they have disturbed consciousness from head injuries and the problem has not been one of the first priorities in management. The long-term management of such problems can be extremely difficult.

Malunion and other temporomandibular joint dysfunctions

Standard osteotomies may restore any occlusal discrepancy due to the malunion; however the temporomandibular joint dysfunctions that produce pain and trismus may in some

patients result in crippling and chronic disruptions to their lives in spite of intensive physiotherapy and long-term pain relief.

CHAPTER 37

Anatomy and physiology of the breast

Giovanni Bistoni¹ and Jian Farhadi²

¹Plastic Surgery Unit, Hospital de la Ribera, Alzira, Spain and Department of General Surgery 'P. Valdoni', Policlinico Umberto I, University of Rome 'Sapienza', Rome, Italy

²Department of Plastic & Reconstructive Surgery, St Thomas' Hospital, London, UK

The mammary gland is an organ of ectodermal origin, typical of mammals, whose structure reflects its special function: the production of milk for lactation. In human beings the breast has an undoubted aesthetic value, having been the inspiration of many kinds of work of art during the centuries. It also has an erotic relevance, the breast being associated in many cultures with sexuality and sensuality.

The size and shape of women's breasts vary considerably. Some women have a large amount of breast tissue and have larger breasts. Others have a smaller amount of tissue with little breast fat. A woman's breasts are rarely the same size; usually one breast is slightly larger or smaller, higher or lower or of different shape to the other.

The inner structure of the mammary gland is made of epithelial components that consist of lobules, where milk is made, which connect to ducts that lead out to the nipple. These lobules and ducts are located and spread throughout the background fibrous tissue and adipose tissue that form the main mass of the breast.

The structure of the male breast is almost identical to that of the female breast, except that the male breast tissue lacks the specialized lobules because there is no physiologic need for milk production.

Development of the breast (embryology)

Human breast tissue begins to develop at approximately the 5th–6th week of fetal life. It proceeds from a single ectodermal bud and starts developing along the ventral side of the embryo in longitudinal bands of thickened ectoderm called *milk lines*, extending from the axilla to the pelvis. Most mammals develop a series of paired mammary glands along this ridge but in humans only a single pair of glands develop in the pectoral region of the milk line by the 9th week of gestation. It is here that a mass of basal cells proliferates to form the nipple bud. Squamous cells from the surface begin to invade the nipple bud

by the 12th week and while the epithelial cells grow downward as mammary ducts, terminating in lobular buds, the mesenchymal cells differentiate into smooth muscle of the nipple and areola. This specialized epithelium buds into 15–20 branches that first consist of solid epithelial columns and then, by the 20th–24th weeks of gestation, develop inner lumen and eventually canalize to form the lactiferous ducts. These branched epithelial tissues are stimulated to canalize by the placental sex hormones that enter the fetal circulation during the third trimester.

The ends of these branches differentiate into lobulo-alveolar structures that contain *colostrum*, which is a yellow, sticky and serous fluid. This colostrum milk, stimulated by the placental hormones, can be expressed for 4–7 days after birth in both male and female newborns ('witch's milk').^{1,2} During the final weeks of gestation the mass of the mammary gland increases consistently and the nipple–areola complex (NAC) develops and becomes pigmented. With the withdrawal of placental hormones after birth, the colostrum secretion stops and the breast starts a sort of involution.

The supporting structure of the breast, composed of connective tissue and fat, originates from the mesenchyme that invades and surrounds the epithelial system.

Failure of some of these stages in breast development to take place can result in congenital abnormalities of the breast. Ectopic breast tissue may be found in 1–6% of individuals.¹ Accessory nipples (polythelia), for example, are not uncommon along the milk line and are most often found on the chest wall below the breast (Figure 37.1). These form due to a failure of the regression of the milk streak. Inverted nipples are not uncommon either, and they are caused by a failure of the evagination of the small mammary pit at birth. Accessory mammary glands (polymastia), also due to a failure of the milk line to completely atrophy, are usually found in the axilla and cause the patient to complain of a mass or pain in this area. Absence of the breast (amastia) is a rare congenital anomaly; it occurs as a result of an arrested mammary ridge at about the 6th week of gestation.^{1–4}

Figure 37.1 The milk line extends from the axilla to the groin. Aberrant breast and/or vestigial nipple and areola development can occur anywhere along this line.

Development of the breast from birth until puberty

During this period the breast consists of lactiferous ducts, with no alveoli. As puberty begins, the circulating oestrogen causes the ductal epithelium and surrounding stroma to grow. These ducts begin to arborize and form collecting ducts and terminal duct lobular units. These ultimately form buds that precede further breast lobules. Surrounding the ducts, vascularity increases and connective tissue increases in volume and elasticity, replacing adipose tissue and providing support for the development of ducts. Breast budding is one of the first sign of adolescence in girls, beginning anywhere between age 8 and 13 years.

Development of the breast during pregnancy

During pregnancy the breast attains its maximum development. Secreting alveoli appear, and there is marked growth of the ducts, lobules and alveoli under the influence of luteal and placental sex steroids and prolactin. During the first weeks, under the influence of oestrogen, there is ductal sprouting and lobular proliferation. By the second month the breasts have enlarged dramatically, with increased nipple and areolar pigmentation.⁵ The alveoli now display a lumen surrounded by the secretory cells. During the second trimester of pregnancy progesterone causes the lobular formation to exceed the ductal sprouting with a notable raise of prolactin levels.^{1,5} At this point the alveoli contain colostrum and the breast continues to enlarge. In the last trimester the stroma surrounding the lobules diminishes to make room for the

hypertrophied lobules and the breast starts secreting colostrum, which is then replaced by true secretion of milk. When lactation ceases, the glandular tissue returns to its resting state.

Development of the breast during menopause

Menopause typically occurs when a woman is in her late 40s and early 50s and it is associated with a variety of symptoms related to the loss of oestrogen and progesterone. The glandular tissue of the breast atrophies, the connective tissue becomes less cellular and the amount of collagen decreases. The loss of strength of the connective tissue usually results in an increase in volume and sag to the breast. However these changes of atrophy are variable and incomplete from woman to woman.

Anatomy of the breast

Breast mound

The breasts are located on the anterior and also partly the lateral aspects of the thorax. Each breast extends superiorly to the second rib, inferiorly to the sixth costal cartilage, medially to the sternum, and laterally to the midaxillary line.^{6,7} The superolateral part of the mammary gland extends towards the axilla, along the lower border of the pectoralis major, forming the axillary tail of Spence. Breast shape and size depend upon genetic, racial and dietary factors, and the age, parity and menopausal status of the individual. Breasts may be hemispherical, conical, variably pendulous, piriform or thin and flattened. Each breast usually assumes a conical form with a base measuring 10–12 cm and a thickness of 5–7 cm.^{3,8} The main bulk of the breast tissue is usually localized to its upper outer quadrant. This is the quadrant more often implicated in breast cancer and in most benign lesions of breast² (Figure 37.2).

The nipple–areola complex

The NAC is located between the fourth and fifth ribs in nulliparous women but its position varies widely when the breasts are pendulous. The complex typically measures 3–4 cm in diameter and is ideally located in the centre of the breast mound. The 15–20 lactiferous ducts open on to the nipple. Both the nipple and the areola consist of keratinizing stratified squamous epithelium with a dense basal melanin deposition. Melanocytes are quite numerous in the skin of the nipple and areola, giving them a darker colour than the remainder of the breast. The areola is a disc of skin that circles the base of the nipple, varying in colour from pink to dark brown depending on parity and race. It contains sebaceous glands, sweat glands and, visibly, accessory glands called *Montgomery's glands*, which open at the periphery of the areola as *Morgagni tubercles* that provide lubrication during lactation.^{3,9,10} Smooth muscle fibres lie underneath the areolar skin; these respond to tactile and autonomic sympathetic stimulation and are responsible for nipple erection and areolar constriction.^{3,11} The NAC is also provided with a rich sensory innervation.

Fascial support and chest wall

Along its deep surface, the breast lies upon the deep pectoral fascia, which in turn overlies pectoralis major and serratus anterior, and inferiorly, external oblique and its aponeurosis as the latter forms the anterior wall of the sheath of rectus abdominis. The fascial relationships of the breast are of practical importance. The superior pectoral fascia, with the anterior layer, envelops the breast ventrally and a posterior layer dorsally. The superficial layer lies immediately beneath the dermis and enables skin flaps to be dissected from the glandular mass of the breast quickly and in a relatively avascular plane.² The deep layer of the superficial pectoral fascia is thicker than the subcutaneous component and lies on the posterior surface of the breast. Between this and the deep pectoral fascia there is a

layer of filmy areolar tissue (*retroamammary bursa*). This is identifiable during mastectomy and allows a bloodless plane of dissection.¹² It also allows the breast to move freely on the underlying fascial covering of the pectoralis major and the serratus anterior. Deep infiltration of a cancer through this space into the underlying pectoralis fascia produces the typical sign of deep tethering of a malignant breast mass.^{2,13}

Connecting these two fascial layers are the *suspensory ligaments of Cooper*, which provide some structural framework to the parenchyma. These ligaments have a degree of laxity and stretch to them that allows breast mobility while maintaining structural integrity. Contraction of this tissue by malignant infiltration results in the characteristic skin dimpling over a carcinoma of the breast (*peau d'orange*).^{2,3,13}

Other additional ligaments that take part in breast suspension have been described. The *ligamentum suspensorium mammae* starts at the clavicle and reaches to the upper border of the breast and the retromammary space.³ It is well defined in some individuals but could be almost indistinct in others. Another ligament structure has been described in recent years: a fibrous bridge exists between the pectoralis muscle and the skin of the inframammary crease. This ligament gives rise to the inframammary fold and acts as a sling for the breast parenchyma.^{14–16} This was found to be continuous with the fifth rib medially and the fascia between the fifth and sixth ribs laterally. Medially, this structure seems to be a condensation of the rectus abdominis fascia and laterally the fascia of the serratus anterior and external oblique muscle. This ligament should be carefully considered during a breast augmentation because preserving the ligament to the bony framework while releasing the pectoralis muscle would minimize the risk of the breast's bottoming out.

A horizontal septum that lies at the level of the fifth rib and traverses the glandular tissue has also been described.^{14–17} This septum becomes thicker along the medial and lateral edges and curves upward into vertically oriented ligaments that attach the breast to the thoracic wall. These ligaments are composed of a superficial and a deep structure and they connect medially to the inframammary crease ligament and laterally to the axillary fascia. The loss of the elastic component in these ligaments or their stretching in time contributes to loss of shape and firmness.

With regard to the rest of the fascia outside the breast area, above the breast, the superior pectoral fascia is continuous with the superficial cervical fascia, whereas at the inferior aspect of the breast, the anterior and posterior layers of the superior pectoral fascia rejoin and are continuous with Camper's and Scarpa's superficial abdominal fascia at the inframammary fold.^{1,13,18} The clavipectoral fascia runs deep to the pectoralis major muscle and surrounds the pectoralis minor muscle. Superiorly, this fascia thickens and attaches to the clavicle. This is an important landmark in surgery because it forms the roof of the axillary space also known as the axillary fascia.^{1,13}

Parenchyma

The breast parenchyma and associated fat make up the bulk of the volume of the breast. The fibroglandular tissue, or parenchyma, of the breast, is divided into 15–20 lactiferous ducts coming from deep within the breast lobules and converging at the nipple in a radial arrangement. These ducts are not always evenly distributed around the breast. The upper half of the breast, particularly the upper outer quadrant, usually contains more glandular tissue than does the rest of the breast. Each duct defines a lobe made of 20–40 lobules, each consisting of 10–100 alveoli. The main duct from each lobe opens separately on the tip of the nipple and possesses a dilated sinus just before its termination in the subareolar tissue. The ductal–lobular unit is the functional unit of the breast. The ducts are lined with stratified squamous epithelium and gradually transition to a double layer, then a single layer of cuboidal cells towards the nipple. The epithelial
